The conditions under which loaded motors will reverse their direction of rotation, will depend upon the characteristics of the motors, their loads and the voltages at their terminals, the latter being influenced by the presence of the motors and other loads on the transformers. Since reversal of the direction of rotation has occurred in practice following the opening of a conductor, it is reasonable to assume that the higher the negative voltage produced on the open phase with the transformer unloaded, the more apt is reversal of the direction of rotation of motors to occur.

Conclusions

1. In a three-phase power system, high sustained voltages may in some cases result from the opening of one or two conductors which separates ungrounded transformers from the rest of the system.

2. The transformer connections (wye or delta) and construction (single-phase, or three-phase core- or shell-type) make little difference in the magnitudes of voltage or in the regions in which high voltages are encountered.

3. High overvoltages can be eliminated in grounded systems by grounding the neutrals of the load transformers.

4. The regions within which abnormal voltages are obtained, are considerably extended by the effects of transformer saturation.

5. The regions wherein voltages in solidly grounded systems in excess of rated line-to-line voltages occur, and therefore of importance in the application of lightning arresters, are for the usual cases confined to ratios of x_{c1}/x_m less than three for one conductor open, and less than six for two conductors open.

6. To avoid the possibility of obtaining unduly high abnormal voltages in solidly grounded systems, single-pole switches or fuses should not be used where the length of line, or equivalent capacitance, between the

break and ungrounded transformers supplying the load is greater than that given by equation 1. Figure 12 can be used directly when the rms exciting current is 3.5 per cent.

7. The highest voltages appear in an ungrounded system with the simultaneous occurrence of an open conductor and line-to-ground fault, such as might correspond to the breaking and falling to ground of a line conductor.

8. From the standpoint of open conductors without faults, the criterion given in conclusion 6 is always conservative for ungrounded systems. However, if the criteria are to include the effects of permanent faults, then it is necessary to impose two approximate requirements, namely, x_{c1}/x_m must be greater than 25.0, and x_{c0}'/x_m must be either less than 0.04 or greater than 40.0. Figures 12 and 14 can be used when the rms exciting current is 3.5 per cent.

9. The voltages arising from open conductors can be calculated with reasonable accuracy by consideration only of the fundamental-frequency components of voltage and current as outlined in the appendix.

Appendix

Analytic Determination of the Sustained Voltage to Ground on Open Conductors in a Circuit Supplying an Unloaded Transformer Bank

Using figures 1*b*, the following additional assumptions will be made:

1. The sustained voltages to be determined are substantially sinusoidal voltages of fundamental frequency.

2. The effective exciting reactance of transformer windings to be used in calculating fundamental-frequency voltages can be determined from the saturation curve of the transformer, determined by applying sinusoidal voltages. The exciting reactance varies with the magnitude of the impressed voltage, but at any voltage, it is the ratio of the rms voltage to the rms current.

3. Resistance in the transformers as well as in the transmission circuit can be neglected.

I. POWER SOURCE SOLIDLY GROUNDED

A—Phase a Open, No Fault

Referring to figure 1*b*, switches S_N, S_b, S_c are closed and S_a and S_L open. No voltage is applied to phase *a* of the three-phase circuit supplying the transformer bank. The voltages to ground, V_b and V_c, applied to phases *b* and *c* in per unit of normal line-to-neutral voltage, with the applied voltage of phase *a* as reference vector, are

$$V_b=-{}^1/_2-j\sqrt{3}/2;\ V_c=-{}^1/_2+j\sqrt{3}/2 \quad (2)$$

Let

V_a = voltage to ground of phase *a* on transformer side of opening in per unit of normal line-to-neutral voltage

V_N = voltage to ground of neutral of wye-connected transformer bank in per unit of normal line-to-neutral voltage

x_m = per unit effective transformer exciting reactance of any winding at normal voltage, either wye or delta-connected

x_{ab}, x_{ac}, x_{bc} = per unit effective transformer exciting reactances of windings *ab*, *ac*, *bc* of delta-connected bank corresponding to voltages across them

x_a, x_b, x_c = per unit effective transformer exciting reactances of windings *a*, *b*, *c* of wye-connected bank corresponding to voltages across them

x_{c1}', x_{c0}', x_{c1}, x_{c0} = per unit positive- and zero-sequence system and circuit line capacitive reactances, respectively, corresponding to C_1', C_0', C_1 and C_0 of figure 1*b*

All reactances are in per unit on a common kilovolt-ampere base. Effective reactances of delta-connected transformer windings, as defined above, are expressed in per unit on normal line-to-line voltage. They are to be multiplied by 3 to be expressed on normal line-to-neutral voltage.

V_b and V_c can be resolved into two components of voltage in quadrature with each other, $-{}^1/_2$ and $-j\sqrt{3}$. The former sends current to ground through phases *b* and *c* in parallel in series with phase *a*. The latter produces equal and opposite currents in phases *b* and *c*. Since the circuit is symmetrical about phase *a* and resistance is neglected, the voltages between neutral and terminals *b* and *c* of a wye-connected transformer bank will be equal in magnitude. Therefore the impedances x_b and x_c are equal. In a delta-connected bank, the voltages between *a* and *b* and *a* and *c* will be equal in magnitude, and therefore x_{ab} and x_{ac} are equal. The component $-j\sqrt{3}$ will produce no voltage at terminal *a*. With resistance neglected, V_a can be positive or negative but will have no quadrature component. In a wye-connected bank, the neutral will likewise have no quadrature component of voltage.

Let

I_a = total current flowing from phase *a* on the transformer side of the opening to ground

I_t = current flowing from transformer bank terminal *a*

x_t = effective exciting reactance of the transformer bank to I_t

With delta-connected primary windings and secondary windings either wye- or delta-connected,

$$x_t=3x_{ab}/2 \quad (3)$$

With wye-connected primary and secondary windings,

$$x_t=x_a+x_b/2 \quad (4)$$

With wye-connected primary windings and delta-connected secondary windings, neglecting leakage reactance, the sum of the three voltages to neutral of the wye must be zero.

$$\therefore V_{aN}=2\ (\text{real part of } V_{Nb})$$

If I_Δ is the circulating current in the delta, assumed opposite to I_t in phase *a*,

$$x_a(I_t-I_\Delta)=2x_b(I_t/2+I_\Delta) \text{ and}$$

$$\therefore I_\Delta=I_t(x_a-x_b)/(x_a+2x_b)$$

The voltage drop through the bank, from *b* to *a* is

$$j(I_t/2+I_\Delta)x_b+j(I_t-I_\Delta)x_a=jI_t[(9/2)x_ax_b\div(x_a+2x_b)]$$

$$\therefore x_t=(9/2)x_ax_b/(x_a+2x_b) \quad (5)$$

The capacitive reactance of the three-phase shunt, C_1-C_0, which is in parallel with x_t is $(3/2)x_{c0}x_{c1}/(x_{c0}-x_{c1})$. The two parallel paths are in series with the capacitance C_0 between phase *a* and ground. I_a is independent of C_1' and C_0'.

$$I_a=-0.5/[-jx_{c0}+j3x_tx_{c1}x_{c0}/\{3x_{c1}x_{c0}-2x_t(x_{c0}-x_{c1})\}] \quad (6)$$

$$V_a=-jx_{c0}I_a=\frac{3x_{c0}x_{c1}-2x_t(x_{c0}-x_{c1})}{2x_t(x_{c1}+2x_{c0})-6x_{c0}x_{c1}} \quad (7)$$

With saturation neglected, $x_t=3x_m/2$ in (3), (4), or (5) and (7) becomes

$$\text{with } x_{c0}=x_{c1},\ V_a=x_{c1}/x_m/(3-2x_{c1}/x_m) \quad (8)$$

$$\text{with } x_{c0}=2x_{c1},\ V_a=(2x_{c1}/x_m-1)\div(5-4x_{c1}/x_m) \quad (9)$$

V_a, calculated from (8), is the ordinate of curves 3 of figures 3*a* and 3*c*; calculated from (9), the ordinate of curves 3 of figures 3*b* and 3*d*.

Effect of Transformer Saturation. (*a*). Delta-connected primary windings, delta- or wye-connected secondary windings. Replacing x_t in (7) by $3x_{ab}/2$, and dividing both numerator and denominator by $3x_{ab}x_{c1}$,

$$V_a=[(x_{c1}/x_{ab})(x_{c0}/x_{c1})-(x_{c0}/x_{c1}-1)]\div[(1+2x_{c0}/x_{c1})-(2x_{c1}/x_{ab})(x_{c0}/x_{c1})] \quad (10)$$

$$|V_{ab}|=\frac{1}{\sqrt{3}}\left|\left(-\frac{1}{2}-V_a\right)-j\frac{\sqrt{3}}{2}\right| =\frac{1}{\sqrt{3}}\sqrt{\left(\frac{1}{2}+V_a\right)^2+\frac{3}{4}} \text{ per unit normal line-to-line voltage} \quad (11)$$

The following procedure can be used to obtain a graph of V_a versus x_{c1}/x_m, when the ratio of x_{c0}/x_{c1} is known.

1. Calculate V_a for an assumed ratio of x_{c1}/x_{ab} from (10).

2. Calculate $|V_{ab}|$ corresponding to V_a from (11).

3. From the given transformer saturation curve, calculate x_{ab}/x_m, the ratio of the reactance at voltage $|V_{ab}|$ to the reactance at normal voltage.

4. x_{c1}/x_m corresponding to V_a is the product of x_{c1}/x_{ab} and x_{ab}/x_m.

Illustration: Let $x_{c0}=2x_{c1}$. Performing the four steps of the procedure given above, indicating each by number:

(1) Assuming $x_{c1}/x_{ab}=1.42$, from (10), $V_a=-2.71$

(2) From (11), $|V_{ab}|=\frac{1}{\sqrt{3}}\sqrt{(-2.21)^2+0.75}=1.37$ per unit of normal line-to-line voltage

(3) From saturation curve 2 of figure 2,

$$x_{ab}/x_m=\frac{\text{rms voltage}}{\text{rms exciting current}}=1.37/8.0=0.172$$

(4) $x_{c1}/x_m=1.42\times0.172=0.244$

The point, $V_a=-2.71$, $x_{c1}/x_m=0.244$, is plotted in curve 2 of figure 3*b*. For no saturation, $x_{ab}/x_m=1$ and $x_{c1}/x_m=1.42$. The point $V_a=-2.71$, $x_{c1}/x_m=1.42$ is plotted in curve 3 of figure 3*b*.

(*b*). Wye-connected primary and secondary windings. The current, I_t, through the wye-connected bank produces voltage drops between b and N, and N and a in the ratio $x_b/2$ to x_a. Replacing x_t in (7) by $x_a+x_b/2$ and dividing numerator and denominator by x_{c1}/x_m,

$$V_a=\frac{(3x_{c1}/x_m)(x_{c0}/x_{c1})+(2x_a/x_m+x_b/x_m)(1-x_{c0}/_{c1})}{(2x_a/x_m+x_b/x_m)(1+2x_{c0}/x_{c1})-6(x_{c1}/x_m)(x_{c0}/x_{c1})} \quad (12)$$

The real part of

$$V_{Nb}=\pm\sqrt{|V_{Nb}|^2-3/4} \quad (13)$$

$$V_{aN}/(x_a/x_m)=\pm\frac{2}{(x_b/x_m)}\sqrt{|V_{bN}|^2-3/4} \quad (14)$$

$$V_a=V_b-V_{Nb}-V_{aN}=-\frac{1}{2}-V_{Nb}\text{ real}-V_{aN} \quad (15)$$

A graph of V_a versus x_{c1}/x_m for a given ratio of x_{c0} to x_{c1} can be obtained by the following procedure:

1. Assume $|V_{Nb}|$, the magnitude of the voltage between transformer terminal b and neutral in per unit of normal. From the given transformer saturation curve, obtain x_b/x_m corresponding to $|V_{Nb}|$.

2. Calculate the real part of V_{Nb} from (13).

3. Obtain the ratio $V_{aN}/(x_a/x_m)$ from (14), and from the given transformer saturation curve find values of $|V_{aN}|$ and (x_a+x_m) which are in this ratio. The sign of V_{aN} is the same as that of the real part of V_{Nb}.

4. Calculate V_a from (15).

5. Knowing V_a, calculate x_{c1}/x_m from the implicit equation (12), after replacing x_{c0}/x_{c1} by its given value.

(*c*). Wye-connected primary and delta-connected secondary windings. This case differs from the preceding in that $x_t=(9/2)\times x_ax_b/(x_a+2x_b)$ and

$$V_{aN}=2V_{Nb}\text{ real} \quad (16)$$

The procedure to determine a graph of V_a versus x_{c1}/x_m is similar to that of case (*b*) except that (16) is used to determine V_{aN}, and x_a/x_m corresponding to $V_{aN}|$ is obtained from the transformer saturation curve. V_a is calculated from (15). With V_a determined, the corresponding value of x_{c1}/x_m can be calculated from (7) if x_t is replaced by its value from (5).

B—Phases b and c Open, No fault

Referring to figure 1*b*, switches S_N and S_a are closed and S_b, S_c, and S_L open. Case *B* differs from case *A*, in that the only voltage applied to the circuit supplying the transformer bank is $V_a=1$; and I_a, the current from phase *a*, flows to ground through C_0 of phases *b* and *c* in parallel. Making these two changes, with V_a as reference vector,

$$V_b=V_c=I_a(-jx_{c0}/2)=-\frac{3x_{c1}x_{c0}-2x_t(x_{c0}-x_{c1})}{2x_t(2x_{c1}+x_{c0})-3x_{c1}x_{c0}} \quad (17)$$

(*a*). *Delta-Connected Primary Windings, Delta- or Wye-Connected Secondary Windings.* Replacing x_t in (17) by $3x_{ab}/2$,

$$V_b=V_c=-\frac{(x_{c1}/x_{ab})(x_{c0}/x_{c1})-(x_{c0}/x_{c1}-1)}{(2+x_{c0}/x_{c1})-(x_{c0}/x_{c1})(x_{c1}/x_{ab})} \quad (18)$$

$$|V_{ba}|=\frac{1}{\sqrt{3}}|V_a-V_b|=\frac{1}{\sqrt{3}}|1-V_b|\text{ times normal line-to-line voltage} \quad (19)$$

Using (18) and (19) instead of (10) and (11), respectively, the procedure for determining a graph of V_b or V_c versus x_{c1}/x_m for a given ratio x_{c0}/x_{c1} is analogous to that for one open conductor.

Wye-Connected Primary Windings. Secondary Windings (b) Wye-Connected, (c) Delta-Connected. The procedure for obtaining a graph of V_b or V_c versus x_{c1}/x_m for a known ratio, x_{c0}/x_{c1}, is analogous to that used for one open conductor, except there is no quadrature component of voltage in V_{Nb}, and equation (17) is used instead of (7).

II. Power Source Ungrounded

If the capacitance to ground of the power source with ungrounded neutral is large relative to that of the transmission circuit and bank, the power source can be considered to have its neutral effectively grounded. Case II then becomes case I. When this is not the case, the zero-sequence capacitance of the power source, C_0', in figure 1*b* must be considered. Under the assumption of balanced line-to-line voltages at $a'b'c'$, the positive-sequence capacitance, C_1', has no effect upon the resulting voltages.

The procedure used in case II is analogous to that given for case I. The voltage which sends current to ground is 1.5 times normal line-to-neutral voltage applied in a loop circuit in which the ground can be considered a single point.

Arcing Faults in Power Systems

C. CONCORDIA
MEMBER AIEE

H. A. PETERSON
ASSOCIATE AIEE

It has for many years been recognized that voltage surges of considerable magnitude could be produced under certain system conditions by switching operations or by arcing faults. Such voltage surges have been studied in some detail in the past, and various theories have been developed to explain their occurrence and to predict their magnitude. The theories were in most cases sound, but the prediction of surge magnitude was on a rather insecure basis.

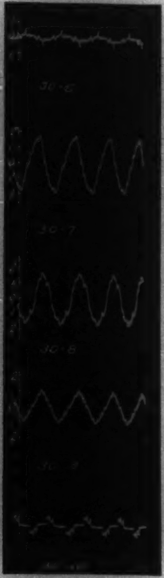

Figure 1. Sustained arcing ground (type 1) on reactance-grounded system

Within the past few years the study of the effect of switching operations in electric circuits has been greatly facilitated by the development of miniature circuits together with equipment for producing regularly recurrent switching and for indicating the resultant surge voltages and currents. This development has made it possible to re-examine on a more exact and physically consistent basis the various theories of intermittent switching and arcing, and to extend very much the range of possibilities investigated. Two recent papers[1,2] have presented preliminary results obtained by this new method of attack on the problem.

Reference 1 presented data on a particular form of arc restriking over a range of system parameters, and a discussion of two other forms of restriking. Reference 2 presented data on four types of arc restriking for a particular system. The present paper extends the work begun in these two references, and presents:

(*a*). Data on several types of arc restriking over a considerable range of system parameters,

(*b*). Data on the effects of various possible sequences of restriking,

(*c*). Data on the effects of various changes in system parameters and in system configuration,

(*d*). Data on the effects of fault and system resistances, and

(*e*). A discussion of the general effect of various methods of system neutral grounding on voltage surges, based on the studies which have been made.

Throughout this study the circuit-interrupting device enters only in so far as its assumed dielectric recovery characteristic determines the point at which restriking takes place, the resulting recovery voltage being otherwise completely determined by the circuit characteristics. Certain types of interrupting devices may modify this resultant recovery characteristic, and therefore the form and magnitude of the surge voltage, considerably.

The miniature circuit used in obtaining most of the data presented is described in reference 5.

Results

(*A*) Five types of arc restriking were studied, and are discussed in turn below.

Type 1. Continuously sustained arc restriking of one phase to ground at the voltage level which results in the highest voltages on the unfaulted phases, the restriking voltage being the same for either polarity. Such restriking may approximate the arcing conditions over an insulator string in the open air, wherein the restriking voltage might wander more or less slowly over the range which can be sustained, as the arc path wanders. In general, the highest restriking voltage which can be sustained gives the highest voltages on the unfaulted phases.

Figure 1 shows the phase and neutral voltages to ground, together with the fault current, for one case studied. In this case successive restriking of alternating polarity took place at half-cycle intervals, while in some of the other cases studied the arc restruck two or three times with the same polarity in each half cycle. In all cases restriking took place whenever the recovery voltage reached the predetermined restrike voltage level, regardless of polarity.

Figures 2–6 give the maximum voltages appearing on either unfaulted phase for restriking of type 1. Curves *C* and *D* of figure 2, for systems with isolated neutral, may be compared with curve *E* to show that these sustained voltages are of the same order of magnitude as the transient voltages appearing on applica-

C—$X_{c0}/X_{l1}=1,120$

tion of a solid fault. Figure 5, for reactance-grounded systems with positive-sequence capacitance C_1 equal to twice the zero-sequence capacitance C_0, shows that for the smaller ratios of zero-sequence reactance X_{l0} to positive sequence reactance X_{l1}, ($X_{l0}/X_{l1}<5$), the voltage on the faulted phase is higher than those on the unfaulted phases. Figures 3–6 indicate that for this type of restriking (*a*) the voltages appearing on systems grounded through reactance are usually greater than those on systems grounded through resistance of the same ohmic value except near the ground-fault-neutralizer reactance, (*b*) the voltages are greater with $C_1=C_0$ than with $C_1=2C_0$, and (*c*) the voltages on resistance-grounded systems are more or less independent of the system natural frequencies in the range studied.

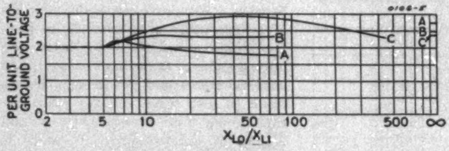

Figure 5. Maximum sustained sound phase voltage for arcing ground of type 1—reactance-grounded system of figure 16—$C_1=2C_0$

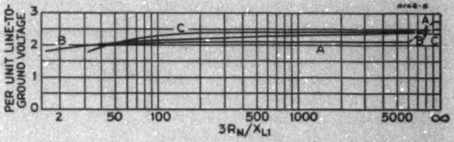

Figure 6. Maximum sustained sound phase voltage for arcing ground of type 1—resistance-grounded system of figure 16—$C_1=2C_0$

A—$X_{c0}/X_{l1}=90$
B—$X_{c0}/X_{l1}=280$
C—$X_{c0}/X_{l1}=1,120$

Type 2. Continuously sustained arc restriking at the voltage levels which result in the highest voltages on the unfaulted phases, without regard to the equality of the restriking voltage of either polarity. This form of restriking has been studied as a convenient representation of possible irregularities in the restriking characteristics. That is, as this particular form of irregularity either increases or does not affect the maximum attainable voltages, there is a basis for concluding that transient variations in the restriking characteristics either are or are not important respectively. Comparison of curves *A* and *B* with curves *C* and *D* in figure 2 (isolated-neutral system) shows a considerable increase in voltage due to inequality of the negative and positive restriking voltage.

The data of figures 2–6 were obtained with an arcing circuit having an inherent dielectric strength recovery characteristic given approximately by the relation:

$$\text{Breakdown voltage} = V(1-e^{-t/T})$$

where

V = maximum breakdown voltage
t = time in microseconds
T = 2,400 microseconds

Thus, if successive restriking occurred several times in a half cycle the restriking voltages of the various restrikes were not all exactly alike, depending on the length of the interval from a current zero to the subsequent restrike. Several check points were taken with the time constant T made very small so that the restriking voltage was truly constant, and little difference could be observed in the magnitudes of the unfaulted phase voltage.

Type 3. Sustained arc restriking of one phase to ground at regular time intervals, in this case at half-cycle intervals. Data on this form of restriking are presented as an indication of what may occur with extremely random, rapid, and large variations in the restriking or flashover voltage. Such restriking is presumably unlikely to occur in an actual system, but could occur under unusual circumstances. The data are included here principally to show that the form of the restriking characteristic, as well as the circuit characteristics, is very important, particularly for systems with isolated neutral. (See figures 7 and 8 for the results obtained. Figure 9 illustrates the building up process leading up to the ultimate sustained maximum voltages of this type.)

Type 4. Transient restriking after interruption of a solid line-to-ground fault. This approximates conditions which may arise on interruption of a faulted conductor by a circuit-interrupting device as described in reference 1. (See figures 10 and 11.)

The sequence of switching operations in figures 10 and 11 is as follows. First, the fundamental-frequency fault current flowing in the arc of the circuit breaker is interrupted at a current zero. The normal recovery voltage then appears across the switch contacts and the arc restrikes at some point on this recovery voltage wave. The consequent restrike current is interrupted at its first current zero, a recovery voltage again appears, restriking takes place a second time, the restrike current is again interrupted at its first cur-

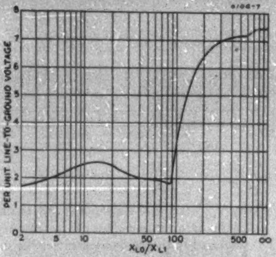

Figure 7. Maximum sustained sound phase voltage for arcing ground of type 3—reactance-grounded system—100-mile line

$C_1=1.6C_0$—0.5 ohm/mile in line neutral—$X_{c0}/X_{l1}=89$
(Ground fault neutralizer at $X_{L0}/X_{L1}=X_{c0}/X_{L1}$)

rent zero, and the final recovery voltage appears. The points at which the restrikes occur are set by trial so as to give the maximum voltage on any phase to ground.

Type 5. Figures 12, 13, and 14 are for the same general type of restriking considered in figures 10 and 11, with the exception that the fault is initially cleared at its first current zero rather than after transient natural frequency oscillations have died out, and illustrate the fact that for circuits of low natural frequency (that is, large inductance and/or capacitance) the most probable manner in which restriking takes place tends to become rather less obvious and thus more difficult to specify, and is moreover increasingly important. For example, one might take as a guide to the selection of a restriking sequence the principle that the dielectric recovery characteristic of the interrupting device never decreases but always either increases or at least remains constant as a function of time. Then restriking could never occur as in figure 13 just after a crest of any oscillatory component of the recovery voltage (that is, when the voltage is decreasing in magnitude), but could occur either before or at a crest as in figure 12. On the other hand, restriking would not necessarily have to occur at or before such a crest, if a later higher crest of either polarity provided a suitable opportunity. It must not be inferred that a decrease of effective voltage breakdown strength with time after a circuit interruption is impossible. In fact, there have been some indications that such action may occur in circuit breakers, especially if their construction and operation allows the dielectric strength to decrease momentarily at any point (for example, by the formation of a bubble of ionized gas) as the contacts part.

Comparison of figures 12, 13, 14, shows the importance of the restriking sequence and illustrates the facts that (*a*) the highest voltages require in general a rather long time (about three or four cycles) to build up, and (*b*) a monotonic dielectric recovery characteristic (figure 12) imposes an appreciable limitation on the magnitude of the voltage surges attainable. (Compare also figures 2–6 with figures 7 and 8 to illustrate this point). It is of interest to compare these results with those of figure 12 (for the one line case) of reference 2, as the systems studied in figures 12–14 of the present paper were very similar, the principal difference being a more exact representation of the line. (See figure 15.)

For most of the systems and types of arcing studied in this paper the maximum surge voltages occur with isolated-neutral systems, minimum points occur with systems grounded either solidly or through ground fault neutralizers, and a second maximum point occurs at a value of neutral reactance equal to about:

(*a*). One-ninth of the ground-fault-neutralizer value for arcing of types 1 and 2,

(*b*). One-sixth of the ground-fault-neutralizer value for arcing of type 3, and

(*c*). One-fiftieth of the ground-fault-neutralizer value for arcing of types 4 and 5.

This second maximum point will occur at greater fractions of the ground-fault-neutralizer value for systems having very low ratios of X_{c0}/X_{l1} (that is, low natural frequencies), for example, in figure 12, reference 2 it occurred at about one-third. In this case, any of the smaller fractions listed as *a*, *b*, *c* above correspond to ratios of zero-sequence reactance X_{l0} to positive-sequence reactance X_{l1} below the critical ratios of figure 5, reference 1, and consequently would not be expected to result in high surge voltages, while the fraction one-third corresponds to a ratio X_{l0}/X_{l1} of approximately 16, which is above the critical ratio.

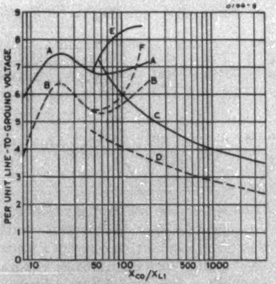

Figure 8. Maximum sustained voltage for arcing ground of type 3—isolated-neutral system of figure 16—$C_1=1.6C_0$

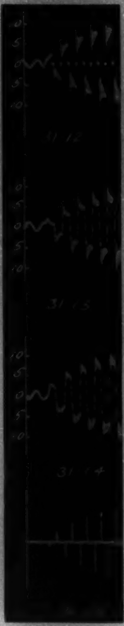
A—Sound phase voltage, 100-mile line
B—Neutral voltage 100-mile line
C—Sound phase voltage, lumped capacitance
D—Neutral voltage, lumped capacitance
E—Sound phase voltage, decreasing line length with X_{l1} constant
F—Neutral voltage, decreasing line length with X_{l1} constant

Figure 9. Build-up of arcing ground (type 3) on isolated-neutral system



(*B*) In addition to the comparison of the effects of several types of arc restriking, the figures also show the effects of various factors in the system configuration as follows:

1. Distribution of system capacitance. The curves of figures 2–6 are for a system as shown in figure 16. Figure 2, for a system with isolated neutral, shows also voltages obtained when the lumped capacitance of figure 16 is replaced by a 100-mile transmission line. It is seen that for a rather large source reactance ($X_{c0}/X_{l1}=8.3$) the surge voltages with the line are greater than with lumped capacitance, while for a smaller source reactance ($X_{c0}/X_{l1}=90$) the reverse is true. (The ratio of zero-sequence

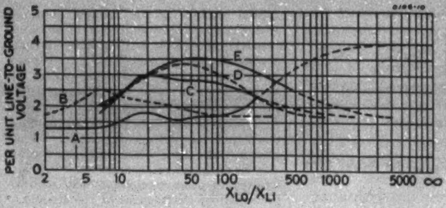


Figure 10. Maximum phase-to-ground voltage for restriking of type 4—reactance-grounded system of figure 16—$C_1 = 1.6C_0$

A—$X_{c0}/X_{l1} = 90$, 100-mile line
B—$X_{c0}/X_{l1} = 300$, 30-mile line
C—$X_{c0}/X_{l1} = 900$, 10-mile line
D—$X_{c0}/X_{l1} = 1{,}800$, lumped capacitance
E—$X_{c0}/X_{l1} = 3{,}900$, lumped capacitance
(Ground fault neutralizer at $X_{L0}/X_{L1} = X_{c0}/X_{L1}$)

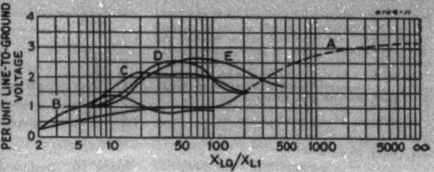

Figure 11. Maximum neutral-to-ground voltage for restriking of type 4—reactance-grounded system of figure 16—$C_1 = 1.6C_0$

A—$X_{c0}/X_{l1} = 90$, 100-mile line
B—$X_{c0}/X_{l1} = 300$, 30-mile line
C—$X_{c0}/X_{l1} = 900$, 10-mile line
D—$X_{c0}/X_{l1} = 1{,}800$, lumped capacitance
E—$X_{c0}/X_{l1} = 3{,}900$, lumped capacitance
(Ground fault neutralizer at $X_{L0}/X_{L1} = X_{c0}/X_{L1}$)

capacitive reactance to positive-sequence inductive reactance was determined without considering the line inductance.) These results suggest that X_{c0}/X_{l1} and C_1/C_0 are not the only factors affecting the phenomena and that therefore an attempt to generalize very much from results obtained from a study of restriking in a simple lumped constant system may sometimes lead to erroneous results. While the trend of the curves of voltage as a function of X_{c0}/X_{l1} given in figure 2 appears to be correct, the maximum voltages possible in an actual system may vary considerably on either side of these curves, depending on system connections.

3. Ratio of positive-sequence capacitance C_1 to zero-sequence capacitance C_0. Figure 2 and comparison of figures 3 and 5 and figures 4 and 6 show that higher voltages are in general obtained for smaller ratios of C_1/C_0. From a different point of view, this confirms the conclusion of reference 1 that systems of lower C_1/C_0 require in general lower values of neutral impedance as far as transient voltage surges are concerned.

It must be pointed out that the effective ratio C_1/C_0 may be less than 1, not only for generators as mentioned in reference 1, but also for transmission lines and systems in general. That is, there is presented to the fault an effective ratio C_1/C_0 which depends on its location along the line and also on the magnitude of the neutral impedance. For example, for a fault at one end of a single unloaded line supplied at the other end from a power source whose reactance is small compared to that of the line, one might expect very roughly on the basis of an equivalent π line an effective ratio C_1/C_0 of about half of 1.6, or 0.8, if the source is ungrounded. This ratio is obtained as follows. The ratio C_1/C_0 for a transmission line as ordinarily defined neglecting line inductance is about 1.6. However, in the positive-sequence circuit viewed from the fault, half of the total positive-sequence capacitance of the equivalent π line is shunted at the source end by the low source reactance, and so may not be very effective as far as disturbances produced by the fault are concerned. On the other hand, in the zero-sequence circuit there is no inductance shunting the part of the capacitance at the source end, if the neutral is isolated. Thus the total zero-sequence capacitance may be effective. If the source is grounded through an impedance the effective capacitance ratio is correspondingly increased, since the neutral impedance is now in shunt with the line capacitance at the source end in the zero-sequence circuit. These considerations bring to light two points:

(*a*). While it is true that the system performance is completely determined by the positive, negative, and zero-sequence networks viewed from the point of fault, one must be cautious in the interpretation and use of the conclusion which apparently follows, that it makes no difference whether, for example, a high ratio of X_{l0}/X_{l1} results from inherent properties of the generating network or from an impedance inserted in the neutral, since insertion of such an impedance may change the effective ratio C_1/C_0 for a given system.

(*b*). The effective capacitance ratio and the capacitance distribution are in general intimately related,

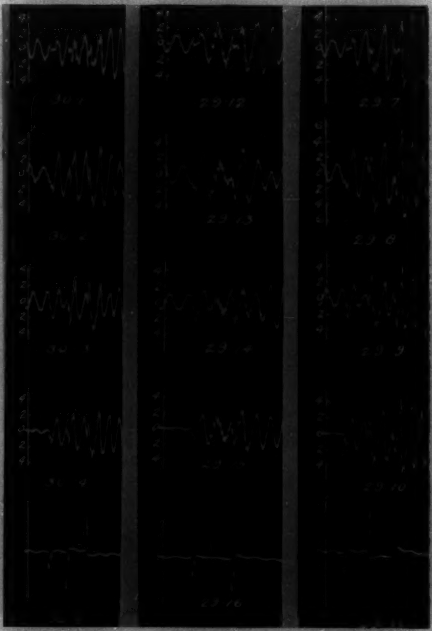

Figure 12 Figure 13 Figure 14

Figures 12, 13, 14. Various restriking sequences (type 5) following interruption of transient line-to-ground fault current—reactance-grounded system of figure 15

so that it may not be possible to specify the probable transient performance by merely stating an over-all system capacitance ratio and noting whether the system capacitance should be classed as lumped or distributed. Instead the actual system configuration may have to be described, and in some cases studied by miniature circuit representation, to obtain a good estimate of its performance.

The voltages of figures 2–8, 10, and 11 may thus be exceeded for systems with the effective value of C_1 less than C_0. The greatest differences may be expected with isolated-neutral systems. Voltages as high as 16 times normal have been obtained for certain system configurations with restriking of type 3 and with $X_{c0}/X_{l1}2\cong 00$. (Compare figure 8, where $C_1/C_0=1.6$ and the corresponding voltage magnitude is 5.2 times normal.) In the limit one approaches the condition of negligible effective C_1 for a "... fault supplied from a rather extensive system through a small and more or less concentrated single reactance .... This reactance may be a transformer or reactor, or even a short length of transmission line or cable".[1] The qualifying words "small" and "short" should here be interpreted as indicating (*a*) a sufficiently high natural frequency with the fault applied, and (*b*) a comparison to the reactance beyond (from the fault) the principal system capacitance. In case of line-to-line faults this latter reactance is the system negative sequence reactance and is seldom large; in case of ground faults, it is the reactance to ground and in the isolated neutral case is infinitely large. Perhaps cable should not be included in the quotation above, because of its usual high ratio of resistance to reactance.

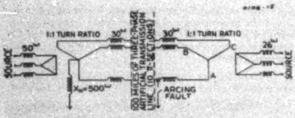

Figure 15. System diagram for figures 12, 13, 14

This discussion of capacitance ratio would be incomplete without mention of the case of a small system, as for example an industrial plant, supplied through a transformer from a large power system. Here the effective ratio of C_1/C_0 may be considerably greater than unity for faults near the supply bus if the supply transformer reactance is small compared to the power system reactance, and thus the allowable neutral reactance will be high. Faults sufficiently far out along feeders so that the supply system reactance becomes small compared to the transformer and feeder reactance revert to the case of C_1/C_0 near unity and therefore require consideration of a proper neutral reactance as indicated in reference 1.

3. Fault resistance. Figure 17 shows the effect of fault resistance in reducing overvoltage caused by arcing grounds of type 2. Figure 18 similarly shows the effect for restriking of type 4. Both figures are for systems with isolated neutral.

The data of figure 17 are for the system of figure 16. A similar study in which 100 miles of artificial transmission line was substituted for the lumped capacitance of figure 16 has shown that fault resistance may at first slightly increase the voltages if:

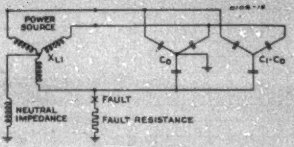

Figure 16. System diagram for figures 1–11 and 17–20

(*a*). X_{c0}/X_{l1} is sufficiently large, for example, 90, and

(*b*). the line has sufficient resistance, for example, $R_1/X_1\cong 0.37$ and $R_0/X_0\cong 1.1$ for the line.

However, a high ratio of X_{c0}/X_{l1} and high line resistance in themselves reduce the voltages, and the voltage with a high line resistance is always less than that with a low resistance.

4. Nonlinear resistor in shunt with neutral reactor. It has been pointed out[1] that resistance in shunt with neutral reactance is beneficial as far as surges resulting from restriking of type 4 are concerned, and that a resistance sufficiently small to produce critical damping of the ground circuit is more than sufficient to prevent successive restriking. It is evident that the shunt resistor can be a nonlinear element such as Thyrite, and figure 19 shows the effect of the degree *n* of nonlinearity on the amount of resistance required. The ratio of required resistance *R* at normal leg voltage to critical damping resistance R_c for a system with high neutral reactance X_{ln} and high natural frequencies is shown to increase as the nonlinearity increases.

5. A gapped resistor such as a lightning arrester can also be used. Figure 20 shows a typical example of the voltages obtained with a reactance-grounded system and with restriking of type 4, as affected by the gap spark-over setting and Thyrite resistance in series with the gap. The ground circuit critical damping value is indicated on the abscissa as $R_c\cong 900$ ohms.

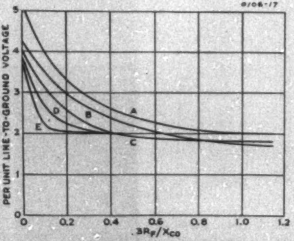

Figure 17. Effect of fault resistance R_F on maximum sound phase voltage for arcing ground of type 2—isolated-neutral system of figure 16—$C_1=C_0$

A—$X_{c0}/X_{l1}=8.2$
B—$X_{c0}/X_{l1}=29$
C—$X_{c0}/X_{l1}=89$
D—$X_{c0}/X_{l1}=290$
E—$X_{c0}/X_{l1}=890$

An arrester is seen to be effective in holding down the surge voltage magnitude. Thus, even in those cases where the surge energy may be sufficient to cause arrester damage, damage to other equipment may still be prevented by the presence of the arrester.

Discussion of the Effects of Neutral Impedance

The results of this and previous papers show that there are many factors which affect the choice of a proper method of grounding, and that all of them must be carefully considered if the best over-all method is to be obtained. These remarks are concerned only with the effects of neutral impedance on voltage surges produced by switching or by arcing faults. Several kinds of switching phenomena may occur, each kind being somewhat differently affected by the method of grounding. For one kind a certain critical value of neutral reactance may be specified, above which it is undesirable to go, for this kind also, resistance grounding is much better and permits much greater impedances to be used. For a second kind, the lower the value of neutral impedance the better, regardless of whether the impedance is reactance or resistance, that is, it is only the magnitude of the neutral impedance which is of importance. For a third kind of switching surge, the surges may increase equally in severity with either neutral reactance or resistance up to a certain point, above which an increase in neutral reactance decreases the severity of the surge while an increase in neutral resistance continues to increase the severity of the surge. A fourth kind is affected very little by neutral impedance.

The first kind of voltage surge includes types 4 and 5 of this paper. Studies have indicated[1] that it is possible to prevent the building up of excessive voltages due to such restriking by:

1. Keeping the reactance under the critical value shown by figure 5 of reference 1,
2. Using a ground fault neutralizer for the neutral reactor,
3. Shunting the reactor by a suitable resistor.

Even if the neutral reactance is obtained by means of a small grounding transformer rather than by a neutral reactor, it may still be possible to use an effective shunt resistor in those cases

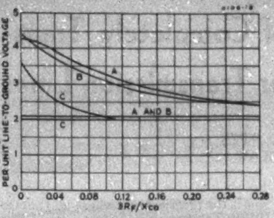

Figure 18. Effect of fault resistance R_F on maximum sound phase voltage for restriking of type 4—isolated-neutral system of figure 16

A—$X_{c0}/X_{l1}=89$, lumped capacitance
B—$X_{c0}/X_{l1}=89$, 100-mile line
C—$X_{c0}/X_{l1}=890$, lumped capacitance

wherein a nearby large transformer is in operation, by putting a resistor in the neutral-to-ground circuit of the large transformer. If the reactance of the large transformer is sufficiently small compared to that of the small grounding transformer, the resistor will be effectively in parallel with the neutral reactance in the zero-sequence circuit. Any case for which such a scheme is proposed should be studied to find out in the first place whether or not it is feasible when the transformer sizes and system connections are considered, and in the second place the required resistance.

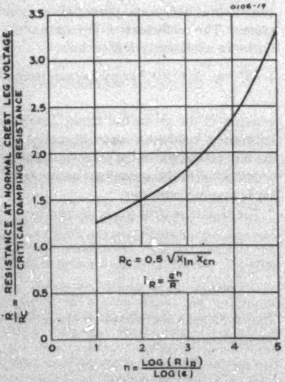

Figure 19. Effect of degree n of nonlinearity on resistance required in shunt with neutral reactor to prevent successive restriking of type 4—$C_1=C_0$

R = shunt resistance at normal leg voltage
R_c = critical damping resistance for ground circuit
X_{ln} = inductive reactance of ground circuit $=X_{l0}/3$ for a three-phase system
X_{cn} = capacitive reactance of ground circuit $=X_{c0}/3$ for a three-phase system
i_R, e = resistor current and voltage

The second kind of voltage surge may arise from restriking of the arc in the unfaulted phase or phases, during the interruption of a double-line-to-ground fault or a solid single-line-to-ground fault, if the unfaulted phase carries principally a line charging current or other capacitance load.[2] For this condition there is no particular critical value of impedance, and studies similar to those of reference 2 have shown very little difference between the performance of resistance or reactance grounding.

The third kind of voltage surge may arise from (*a*) restriking in the unfaulted phases during the interruption of an arcing single-line-to-ground fault if the unfaulted phase involved carries principally a capacitance current, or (*b*) from the arcing ground itself. The points of minimum voltage occur with solid grounding and with a ground fault neutralizer. The minimum at the ground-fault-neutralizer value in the voltage caused by restriking in the unfaulted phases occurs because there should be very little occasion to interrupt an arcing single-line-to-ground fault in systems equipped with ground fault neutralizers.

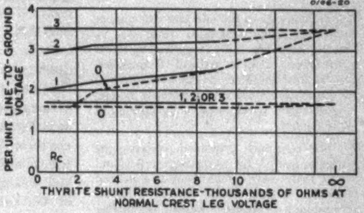

Figure 20. Effect of gapped Thyrite in shunt with neutral reactor on maximum sound phase voltage for restriking of type 4—reactance-grounded system of figure 16

$X_{l0}=557$ ohms
$X_{l1}=13.9$ ohms
$X_{c0}=53{,}000$ ohms
$X_{c1}=33{,}100$ ohms
$X_{l0}/X_{l1}=40$ ohms
$X_{c0}/X_{l1}=3{,}820$ ohms
R_c = ground circuit critical damping resistance
Upper four curves—two restrikes
Lower two curves—no restrikes
Numbers on curves are per unit breakdown voltage of gap

The fourth kind may arise in the interruption of the line charging current of an unfaulted line. Here also, if a rather large portion of the total system capacitance is being switched off, the surges may be somewhat reduced when a ground fault neutralizer is used.[2]

In these last two kinds of switching surges, the effects of neutral impedance in general become smaller as the amount of capacitance being switched off becomes a smaller portion of the total system capacitance.

Other factors which should be considered in evaluating the importance of these surges are the energy content and relative probability of occurrence of the various kinds. For example, if a high voltage appearing on a line due to any of the last three kinds causes a lightning arrester to function, damage to the arrester will not result unless the surge energy (which may be principally determined by the capacitance or length of line involved) is sufficiently great. On the other hand, surges of the first kind are known to have caused arrester damage and breaker failure. The interruption of line charging current is also known to require in many cases rather long clearing times, and in some cases to result in high surge voltages. In at least one case it has caused the operation of protector tubes. Some studies of the clearing of faulted lines[4] have shown restriking only in the faulted phase.

No mention has been made here of the usual voltage transients occurring on application of solid faults, as these have been treated in reference 3. It is emphasized that this discussion is very general and that a great many exceptions can be taken in particular instances.

Conclusions

The principal conclusions to be drawn from the work done so far are:

1. The results obtained cannot always be generalized to make them applicable to all systems. Certain general principles and effects have been discussed in order to show the trends in voltage surge severity which may be expected, but in particular instances it may be advisable to study the system in question (possibly by means of miniature circuit representation), rather than to estimate the probable effects from general data. This is particularly true in evaluating quantitatively the effect of

lightning arresters or other resistors in reducing the magnitude of voltage surges.

2. The effects of the distribution of capacitance within a power system are most pronounced in isolated neutral systems and with arc restriking of type 3.

3. For most of the systems and types of arcing studied, resistance grounding results in lower switching surge voltages than reactance grounding except at, and in the region immediately below, the ground fault neutralizer impedance.

4. For either reactance or resistance-grounded systems the voltages caused by switching surges are not greatly different from those arising from simple application or removal of a solid fault.

5. For isolated-neutral systems, voltages very much higher than those arising from simple application or removal of a solid fault may occur with certain types of arc restriking.

6. In many cases the effective capacitance ratio C_1/C_0 and reactance ratio X_{t0}/X_{t1} viewed from the fault, together with the approximate circuit natural frequencies, can be used as guides to the evaluation of the probable severity of switching surges; it is necessary in all cases to consider all of these factors.

7. For reactance grounded systems the voltages caused by switching surges and arcing faults have a maximum at a neutral reactance of from about $^1/_{10}$ to $^1/_3$ of the ground-fault-neutralizer value, depending on the type of arc restriking and on the circuit natural frequencies.

8. From the standpoint of switching surges and arcing faults, methods of system grounding which should be satisfactory are:

(*a*). Solid grounding.

(*b*). Grounding through moderate values of resistance.

(*c*). Grounding through a ground-fault-neutralizer, with lightning-arrester protection, and

(*d*) Grounding through moderate values of reactance, if a study of the system in question, based on the considerations treated above, indicates that unduly high surges will not result.

If a very low neutral reactance is used (for example, if the resulting ratio of X_{t0}/X_{t1} is less than about 5) a detailed study should not be necessary.

9. For the interruption of open lines, circuit breakers should be used which have a minimum tendency to restrike.

Transient Analysis of Completely Transposed Multiconductor Transmission Lines

LOUIS A. PIPES
ASSOCIATE AIEE

Synopsis: Starting with the general equations of the completely transposed *n*-conductor transmission system expressed in matrix form, the equations are subjected to a similarity transformation. This transformation reduces the general equations to a set of *n* independent equations. These equations are then subjected to a Laplacian transformation and solved subject to the impression of arbitrary electromotive forces at a certain point of the lines. Expressions are obtained for the resulting traveling waves of voltage and current and the velocities of propagation are discussed.

CONSIDERABLE effort has been expended in the transient analysis of multiconductor transmission lines.[1–4] It is the purpose of this paper to extend the theory of the practical case of perfect transposition. The effect of resistance and leakage conductance is considered in the general case. The analysis is greatly facilitated by the use of matrix algebra and the Laplacian transformation. The elements of matrix algebra and the Laplacian transformation presented in references 5 and 6 will be assumed in the discussion.

I. The General Equations

Let us consider a system of *n* long, parallel, widely separated, cylindrical conductors over an equipotential ground plane. It may be shown[1] that the equations governing the distribution of potentials and currents of the system are:

$$-\frac{\partial}{\partial x}(e)=[R](i)+[L]\frac{\partial}{\partial t}(i) \qquad (1)$$

$$-\frac{\partial}{\partial x}(i)=[G](e)+[C]\frac{\partial}{\partial t}(e) \qquad (2)$$

where (e) and (i) are columnar matrices whose elements $e_r(x, t)$ and $i_r(x, t)$, $r=1, 2, \ldots n$ are the potentials to ground and the currents of the several conductors respectively.

The case to be considered in this discussion is the practical case where all the conductors are identical and perfectly transposed with respect to each other and to the ground plane. In such a case we have:

$$[R]=\begin{Vmatrix} R_0 & \cdots & \cdots & 0 \\ 0 & R_0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & \cdots & \cdots & R_0 \end{Vmatrix} \qquad (3)$$

where R_0 is the series resistance of each conductor per unit length. $[L]$ is a square matrix of the *n*th order of the form:

$$[L]=\begin{Vmatrix} L_0 & L & L \ldots\ldots & L \\ L & L_0 & L \ldots\ldots & L \\ \cdots & \cdots & \cdots & \cdots \\ L & L & L \ldots\ldots & L_0 \end{Vmatrix} \qquad (4)$$

where L_0 is the self-induction coefficient of the various conductors defined by:

$$L_0=[^1/_2+2\log_e(2h/r)]10^{-9} \text{ henry per centimeter} \qquad (5)$$

r is the radius of the conductors and h is the geometric mean height of the conductors above the zero potential ground plane. The coefficients L are mutual inductance coefficients defined by:

$$L=2[\log_e(a/b)]10^{-9} \text{ henry per centimeter} \qquad (6)$$

where a is the geometric mean distance between a conductor and the image of another conductor in the process of transposition. b is the geometric mean spacing between conductors.

The square matrix $[G]$ is defined by:

$$[G]=\begin{Vmatrix} G_0 & G & G \ldots\ldots & G \\ G & G_0 & G \ldots\ldots & G \\ \cdots & \cdots & \cdots & \cdots \\ G & G & G \ldots\ldots & G_0 \end{Vmatrix} \qquad (7)$$

The coefficients are defined by the following equations:

$$G_0=g_0+(n-1)g \qquad (8)$$

$$G=-g \qquad (9)$$

g_0 is the leakage conductance per unit length to ground of the several conductors. g is the leakage conductance per unit length between the conductors.

The matrix $[C]$ is a square matrix of the *n*th order and has the form:

$$[C]=\begin{Vmatrix} C_0 & C & C \ldots\ldots & C \\ C & C_0 & C \ldots\ldots & C \\ \cdots & \cdots & \cdots & \cdots \\ C & C & C \ldots\ldots & C_0 \end{Vmatrix} \qquad (10)$$

Paper 40-108, recommended by the AIEE committee on basic sciences, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940 and at the Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted October 25, 1939; made available for preprinting May 17, 1940.

Louis A. Pipes is faculty instructor at Harvard University, Cambridge, Mass.

[1] For all numbered references, see list at end of paper.

The $[C]$ matrix is related to an $[S]$ matrix of the form:

$$[S]=\begin{Vmatrix} S_0 & S & S\ldots\ldots S \\ S & S_0 & S\ldots\ldots S \\ \ldots & \ldots & \ldots\ldots\ldots \\ S & S & S\ldots\ldots S_0 \end{Vmatrix} \tag{11}$$

called the elastance matrix by the following equation:

$$[C]=[S]^{-1} \tag{12}$$

The coefficients of the elastance matrix are defined by:

$S_0=18\times10^{11}\log_e(2h/r)$ darafs per centimeter (13)

$S=18\times10^{11}\log_e(a/b)$ darafs per centimeter (14)

where the quantities h, r, a, and b have been defined above.

II. Discussion of the Line Parameters

The formulation of the n transmission line problem by the matrix equations 1 and 2 is a generalization of the engineering treatment of the single-line problem. The complexity of the n conductor problem is such that an analysis based on the Maxwell field equations is practically impossible, hence a simplified treatment based on the Maxwell coefficients of capacity and induction must be undertaken. The question of the validity of such a procedure naturally arises. A qualitative discussion of the principles involved is helpful in making clear the approximations which are introduced.

(*a*). The Coefficients of Induction

The coefficients of self- and mutual-induction as given by equations 5 and 6 are based on the following assumptions:

1. The neglection of radiation from the system. This amounts to saying that we are dealing with a quasi-stationary process and that the displacement current term in the field equations may be neglected.

2. The mean spacing of the conductors is so great that we may neglect the "proximity effect". This effect would tend to disturb the symmetrical distribution of current in the wires on which the calculation of the induction coefficients is based.

3. The "skin effect" is neglected. The factor of $^1/_2$ in the coefficients of self-induction in equation 5 is obtained on the basis of uniform current distribution inside the conductors. This is correct for solid conductors only for the case of zero frequency. At high frequencies or for traveling waves, the skin effect is so great that there cannot be any penetration of the current into the conductors. Hence the factor of $^1/_2$ must be neglected in such cases. In the "dissipationless" case of no conductor resistance, the factor $^1/_2$ must be neglected at all frequencies since in this case there is no penetration of current into the wires.

(*b*). The Coefficients of Capacitance

The coefficients of capacitance vary so little with frequency that they may be considered constant even with an appreciable amount of conductor resistance present. Although theoretically the capacitance matrix is given very accurately by the reciprocal of the elastance matrix whose elements are specified by equations 13 and 14, yet the capacitance parameters do vary with frequency or steepness of wave front slightly. This is because the theory does not include the effect of insulators, pins, and crossarms which are essential to the support of the lines. Metal pins introduce additional lumped capacitances at the supports. The resultant circuit is quite complex and may be approximately represented by a ladder network. There is some evidence that the capacitance coefficients are functions of the potentials of the conductors when the line potentials are above the critical corona potentials, however it has been found sufficient to take into account the effect of corona by modifying the leakage coefficients.

It may be also noted that in the case of an imperfectly conducting earth, the height h to ground of equation 13 differs from that of equation 5 which must be taken as the height above an equivalent conducting mass which represents the effect of the ground.

(*c*). The Resistance Coefficients

The theoretical variation of the resistance parameters with the steepness of the front of traveling current waves is due to changes in the distribution of internal flux linkages in the conductors. The transient skin effect tends to crowd the current towards the surface in all radial directions. This tends toward an infinite surface density of current for very steep wave fronts. This effect, therefore, tends to increase the conductor resistance with frequency over its direct current value.

(*d*). The Leakage Parameters

Below the critical corona voltage, the leakage parameters may be determined by measurement and regarded as constant. They of course depend greatly on the condition of the insulation and whether the weather is dry or wet. Above the disruptive corona point, the leakage parameters may be regarded as functions of the line potentials. It is customary to simplify the analysis by assuming certain magnitudes of the leakage coefficients that will give the same energy loss per unit length as the actual corona discharge determined by experiment. The problem is one of the utmost complexity and the best that can be done is to assume certain values for the leakage parameters that appear reasonable.

III. Transformation of the Canonical Equations

The canonical equations 1 and 2 will now be transformed by means of the nonsingular, symmetric matrix $[A]$ defined by:

$$[A]=[A_{rs}] \tag{15}$$

where

$r=1, 2, \ldots n \quad s=1, 2, \ldots n$

and

$$A_{rs}=a^{-(r-1)(s-1)} \tag{16}$$

$$a=\epsilon^{j2\pi/n} \tag{17}$$

This transformation matrix $[A]$ occupies a central position in the theory of symmetrical components. The various rows of $[A]$ are the sequence operators of Fortescue.

The transformation matrix $[A]$, is thus a square matrix of the nth order with the important properties that:

$$[A]'=[A] \tag{18}$$

where $[A]'$ is the transposed matrix of $[A]$.

$$[A]^{-1}=\frac{1}{n}[\text{conj } A] \tag{19}$$

where $[A]^{-1}$ is the inverse of $[A]$ and $[\text{conj } A]$ is the conjugate of $[A]$. Let us now premultiply equations 1 and 2 by $[A]^{-1}$, we thus obtain:

$$-\frac{\partial}{\partial x}[A]^{-1}(e)=[A]^{-1}[R][A][A]^{-1}(i)+[A]^{-1}[L][A][A]^{-1}\frac{\partial}{\partial t}(i) \tag{20}$$

$$-\frac{\partial}{\partial x}[A]^{-1}(i)=[A]^{-1}[G][A][A]^{-1}(e)+[A]^{-1}[C][A][A]^{-1}\frac{\partial}{\partial t}(e) \tag{21}$$

Now, if we define:

$$(e)_s=[A]^{-1}(e)=(e_{rs}) \quad r=1, 2, \ldots n \tag{22}$$

$$(i)_s=[A]^{-1}(i)=(i_{rs}) \quad r=1, 2, \ldots n \tag{23}$$

$$[R]_s=[A]^{-1}[R][A]=\begin{Vmatrix} R_0 & 0 & 0\ldots 0 \\ 0 & R_0 & 0\ldots 0 \\ \ldots & \ldots & \ldots \\ 0 & 0 & 0\ldots R_0 \end{Vmatrix} \tag{24}$$

$$[L]_s=[A]^{-1}[L][A]=\begin{Vmatrix} [L_0+(n-1)L] & 0\ldots\ldots & 0 \\ 0 & (L_0-L)\ldots & 0 \\ \ldots & \ldots & \ldots \\ 0 & 0 & (L_0-L) \end{Vmatrix} \tag{25}$$

$$[G]_s=[A]^{-1}[G][A]=\begin{Vmatrix}[G_0+(n-1)G] & 0\ldots\ldots & 0\\ 0 & (G_0-G)\ldots\ldots & 0\\ \ldots\ldots & \ldots\ldots & \ldots\ldots\\ 0 & 0 & (G_0-G)\end{Vmatrix} \qquad (26)$$

$$[C]_s=[A]^{-1}[C][A]=\begin{Vmatrix}[C_0+(n-1)C] & 0\ldots\ldots & 0\\ 0 & (C_0-C)\ldots\ldots & 0\\ \ldots\ldots & \ldots\ldots & \ldots\ldots\\ 0 & 0 & (C_0-C)\end{Vmatrix} \qquad (27)$$

Then we may write (20) and (21) in the form:

$$-\frac{\partial}{\partial x}(e)_s=[R]_s(i)_s+[L]_s\frac{\partial}{\partial t}(i)_s \qquad (28)$$

$$-\frac{\partial}{\partial x}(i)_s=[R]_s(e)_s+[C]_s\frac{\partial}{\partial t}(e)_s \qquad (29)$$

In view of the diagonal form of the matrices $[R]_s$, $[L]_s$, $[G]_s$, and $[C]_s$, the matrix equations 28 and 29 separate into the scalar equations:

$$-\frac{\partial e}{\partial x}1s=R_0i_{1s}+[L_0+(n-1)L]\frac{\partial i}{\partial t}1s \qquad (30)$$

$$-\frac{\partial i}{\partial x}1s=[G_0+(n-1)G]e_{1s}+[C_0+(n-1)C]\frac{\partial e}{\partial t}1s \qquad (31)$$

and

$$-\frac{\partial e}{\partial x}rs=R_0i_{rs}+(L_0-L)\frac{\partial i}{\partial t}rs \qquad r=2,3,\ldots n \qquad (32)$$

$$-\frac{\partial i}{\partial x}rs=(G_0-G)e_{rs}+(C_0-C)\frac{\partial e}{\partial t}rs \qquad (33)$$

IV. Introduction of a Laplacian Transformation

Following the methods of reference 6, part III, let us introduce the quantities $E_{rs}(x, p)$ and $I_{rs}(x, p)$ by means of the equations:

$$E_{rs}(x,p)=p\int_0^\infty e^{-pt}e_{rs}(x,t)dt \qquad r=1,2,\ldots n \qquad (34)$$

$$I_{rs}(x,p)=p\int_0^\infty e^{-pt}i_{rs}(x,t)dt \qquad r=1,2,\ldots n \qquad (35)$$

Or using the symbolic notation of Van der Pol, we write:

$$E_{rs}(x,p)\div e_{rs}(x,t) \qquad (36)$$

$$I_{rs}(x,p)\div i_{rs}(x,t) \qquad (37)$$

for the Laplacian transforms of e_{rs} and i_{rs}.

The equations 30–33 are of the type:

$$-\frac{\partial e}{\partial x}(x,t)=Ri(x,t)+L\frac{\partial i}{\partial t}(x,t) \qquad (38)$$

$$-\frac{\partial i}{\partial x}(x,t)=Ge(x,t)+C\frac{\partial e}{\partial t}(x,t) \qquad (39)$$

Following the methods of part III*B* of reference 6, it is easy to show that the equations satisfied by the transforms of $e(x, t)$ and $i(x, t)$ of (38) and (39) are of the type:

$$-dE/dx=RI+LpI \qquad (40)$$

$$-dI/dx=GE+CpE \qquad (41)$$

provided we assume no initial distribution of potential or current along the line. If we let:

$$e(0,t)\div E_0(p) \text{ at } x=0 \qquad (42)$$

$$i(0,t)\div I_0(p) \text{ at } x=0 \qquad (43)$$

the solution of the simultaneous equations 40 and 41 may be easily shown to be:

$$E(x,p)=E_0(p)\cosh(ax)-ZI_0(p)\sinh(ax)/a \qquad (44)$$

$$I(x,p)=I_0(p)\cosh(ax)-E_0(p)\sinh(ax)/Z_0 \qquad (45)$$

where:

$$Z=Lp+R \qquad (46)$$

$$Y=Cp+G \qquad (47)$$

$$a=(ZY)^{1/2} \qquad (48)$$

$$Z_0=(Z/Y)^{1/2} \qquad (49)$$

In the absence of impressed current at $x=0$, we have $i(0, t)=0$ and hence the above equations reduce to:

$$E(x,p)=E_0(p)\cosh(ax) \qquad (50)$$

$$I(x,p)=-E_0(p)\sinh(ax)/Z_0 \qquad (51)$$

Returning now to the equations 30–33 we have as a solution for the transforms:

$$E_{1s}(x,p)=E_{1s}^0(p)\cosh(a_1x) \qquad (52)$$

$$I_{1s}(x,p)=-E_{1s}^0(p)\sinh(a_1x)/Z_{01} \qquad (53)$$

where $E_{1s}^0(p)$ is the transform of the symmetrical component of voltage at the point $x=0$. An explicit equation for it will be given in a later section, and:

$$a_1=\sqrt{([L_0+(n-1)L]p+R_0)\times([C_0+(n-1)C]p+[G_0+(n-1)G])} \qquad (54)$$

$$Z_{01}=\sqrt{([L_0+(n-1)L]p+R_0)\div([C_0+(n-1)C]p+[G_0+(n-1)G])} \qquad (55)$$

and also:

$$E_{rs}(x,p)=E_{rs}^0(p)\cosh(a_2x) \qquad (56)$$

$$I_{rs}(x,p)=-E_{rs}^0(p)\sinh(a_2x)/Z_{02} \qquad r=2,3,\ldots n \qquad (57)$$

$$a_2=\sqrt{[(L_0-L)p+R_0][(C_0-C)p+(G_0-G)]} \qquad (58)$$

$$Z_{02}=\sqrt{[(L_0-L)p+R_0]/[(C_0-C)p+(G_0-G)]} \qquad (59)$$

The quantities $E_{rs}^0(p)$ are the transforms of the e_{rs} quantities at $x=0$.

V. The Dissipationless Case

(*a*). THE VOLTAGE WAVES

We shall first consider the ideal case of no resistance or leakage. This is the dissipationless case in which no energy is lost in the system.

For this case we have:

$$R_0=G_0=G=O \qquad (60)$$

We therefore have:

$$a_1=p\sqrt{[L_0+(n-1)L][C_0+(n-1)C]}=pb_1 \qquad (61)$$

$$E_{1s}(x,p)=E_{1s}^0(p)[e^{pb_1x}+e^{-pb_1x}]/2 \qquad (62)$$

In view of one of the basic theorems in the theory of the Laplacian transformation (reference 6, part I), which may be stated in the form:

$$\text{If } g(p)\div h(t) \qquad (63)$$

then

$$e^{-kp}g(p)\div\begin{cases}0 & t<k \quad k>0\\ h(t-k) & t>k\end{cases} \qquad (64)$$

it is seen that the term $e_{1s}(x, t)$ is composed of two waves, one traveling in the positive x direction and another one in the negative x direction. The positive wave has the magnitude:

$$e_{1s}^0(t-b_1x)/2=e_{1s}^+ \qquad (65)$$

and the negative wave has the magnitude:

$$e_{1s}^0(t+b_1x)/2=e_{1s}^- \qquad (66)$$

the velocity of propagation of the waves is:

$$v=1/b_1=\{[L_0+(n-1)L][C_0+(n-1)C]\}^{-1/2} \qquad (67)$$

In the case of the no-loss line there is no penetration of the current into the conductor and hence there is no internal magnetic field. The factor of $1/2$ in equation 5 is not present since this is due to the internal magnetic field in the conductors. We thus must have:

$$L_0=2\times10^{-9}\log_e(2h/r) \text{ henry per centimeter} \qquad (68)$$

Comparing this with (13) we see that we may write:

$$L_0=S_0/v_0^2 \qquad (69)$$

where v_0 is the velocity of light in a vacuum and equals 3×10^{10} centimeters per second.

Comparing (6) and (14) we see that we may also write:

$$L=S/v_0^2 \qquad (70)$$

From the relation 12 it may be shown that:

$$C_0=[S_0+(n-2)S]/(S_0-S)[S_0+(n-1)S] \qquad (71)$$

and

$$C=S(S-S_0)^{n-2}/(S_0-S)^{n-1}[S_0+(n-1)S] \tag{72}$$

Substituting the relations (69), (70), (71), and (72) into (67) we obtain:

$$v=v_0 \tag{73}$$

This shows that the forward and backward waves of equations 65 and 66 are propagated with the velocity of light.

It may be similarly shown that the group of waves whose transforms are given by the equations 56 are also propagated with the velocity of light in this dissipationless case.

(*b*). The Current Waves

From the equation 53 we see that we have current waves associated with the voltage waves. We have:

$$i_{1s}^+=e_{1s}^0(t-x/v_0)/2Z_{01} \tag{74}$$

for the forward traveling wave along the positive x direction and

$$i_{1s}^-=-e_{1s}^0(t+x/v_0)/2Z_{01} \tag{75}$$

for the negative traveling wave of current. For the dissipationless case we have:

$$Z_{01}=\{[L_0+(n-1)L]/[C_0+(n-1)C]\}^{1/2} \tag{76}$$

The equations 57 give a set of forward and backward traveling waves of current of the form:

$$i_{rs}^+=e_{rs}(t-x/v_0)/2Z_{02} \quad r=2,3,\ldots n \tag{77}$$

in the positive x direction and:

$$i_{rs}^-=-e_{rs}^0(t-x/v_0)/2Z_{02} \quad r=2,3,\ldots n \tag{78}$$

in the negative x direction. Where:

$$Z_{02}=[(L_0-L)/(C_0-C)]^{1/2} \tag{79}$$

Let us introduce the matrix:

$$(e^+)_s={}^1/_2(e_{rs}^+) \quad r=1,2,\ldots \tag{80}$$

the elements of this matrix are the symmetrical components of the traveling waves of voltage in the positive direction of the system.

The actual positive traveling waves of the system are given by the elements of the matrix:

$$(e^+)=[A]^{-1}(e^+)_s \tag{81}$$

Now if the elements of the matrix (e^0) defined by:

$$(e^0)=e_r^0(t) \quad r=1,2,\ldots n \tag{82}$$

are the impressed voltages on the lines at the point $x=0$, then the symmetrical components of these voltages are given by:

$$(e^0)_s=[A]^{-1}(e^0) \tag{83}$$

Now in view of (80) we may also write:

$$(e^+)_s=\{e^0(t-x/v_0)\}_s/2 \tag{84}$$

and hence:

$$(e^+)_s=\frac{1}{2}[A]^{-1}\{e^0(t-x/v_0)\} \tag{85}$$

By (83) the actual positive traveling waves of voltage are given by:

$$\begin{aligned}(e^+)&=\frac{1}{2}[A][A]^{-1}\{e^0(t-x/v_0)\}\\&=\frac{1}{2}\{e^0(t-x/v_0)\}\end{aligned} \tag{86}$$

Hence we see that in the perfectly transposed line the impressed electromotive forces are propagated in both directions with the velocity of light without distortion or interference provided there is no dissipation.

Let us now define the matrix $(i^+)_s$ whose elements are the symmetrical components of the current waves traveling in the positive x direction by the equation:

$$(i^+)_s=\begin{Vmatrix}1/Z_{01} & 0 & 0\ldots.0\\ 0 & 1/Z_{02} & 0\ldots.0\\ \cdots & \cdots & \cdots\\ 0 & 0 & 0\ldots.1/Z_{02}\end{Vmatrix}(e^+)_s \tag{87}$$

This equation follows from (74), (77), and (80). If we let:

$$[u]=\begin{Vmatrix}1/Z_{01} & 0 & 0\ldots\ldots0\\ 0 & 1/Z_{02} & 0\ldots\ldots0\\ \cdots & \cdots & \cdots & \cdots\\ 0 & 0 & 0 & 1/Z_{02}\end{Vmatrix} \tag{88}$$

then the actual current waves traveling in the positive direction are given by the elements of the matrix:

$$(i^+)=\frac{1}{2}[A][u][A]^{-1}\{e^0(t-x/v_0)\} \tag{89}$$

It is thus apparent that in the case of no dissipation, impressing potential waves at a point of a transmission line results in the propagation of voltage and current waves in the positive and negative directions. These waves are all propagated with the velocity of light and are given by equations 86 and 89.

VI. The General Case (Dissipation Included)

Let us introduce the notation:

$$L_1=L_0+(n-1)L \tag{90}$$

$$C_1=C_0+(n-1)C \tag{91}$$

$$G_1=G_0+(n-1)G \tag{92}$$

$$L_2=(L_0-L) \tag{93}$$

$$C_2=(C_0-C) \tag{94}$$

$$G_2=(G_0-G) \tag{95}$$

Then we may write (54), (55), (58), and (59) in the form:

$$a_1=[(L_1p+R_0)(C_1p+G_1)]^{1/2} \tag{96}$$

$$Z_{01}=[(L_1p+R_0)/(C_1p+G_1)]^{1/2} \tag{97}$$

$$a_2=[(L_2p+R_0)(C_2p+G_2)]^{1/2} \tag{98}$$

$$Z_{02}=[(L_2p+R_0)/(C_2p+G_2)]^{1/2} \tag{99}$$

The equation 52 for the transform of the symmetrical component voltage waves may be written in the form:

$$E_{1s}(x,p)=E_{1s}^0(p)[e^{a_1x}+e^{-a_1x}]/2 \tag{52}$$

We can therefore write:

$$E_{1s}^+(x,p)=E_{1s}^0(p)e^{-a_1x}/2 \tag{100}$$

for the transform of the wave moving in the positive x direction. Similarly we have for the negative wave, the equation:

$$E_{1s}^-(x,p)=E_{1s}^0(p)e^{+a_1x}/2 \tag{101}$$

The transforms of the equation 100 must be computed. Since

$$e_{1s}^0(t)\div E_{1s}^0(p) \tag{102}$$

and $e_{1s}^0(t)$ is given explicitly from the known impressed voltages at $x=0$ as given by (83), we may compute the inverse transform.

To do this, we may use the Faltung theorem of the Laplacian transformation theory (reference 6, part I). This theorem states that if

$$g_1(p)\div h_1(t) \tag{103}$$

and

$$g(_2p)\div h_2(t) \tag{104}$$

then

$$g_1g_2/p\div\int_0^t h_1(u)h_2(t-u)du \tag{105}$$

In a similar manner, the expression (53) for the transform of the currents may be written in the form:

$$I_{1s}(x,p)=E^0(x,p)[e^{-a_1x}-e^{a_1x}]/2Z_{01} \tag{53}$$

and we can write:

$$I_{1s}^+(x,p)=E_{1s}^0(p)e^{-a_1x}/2Z_{01} \tag{106}$$

for the transform of the current wave moving in the positive x direction and:

$$I_{1s}^-(x,p)=-E_{1s}^0(p)e^{a_1x}/2Z_{01} \tag{107}$$

for the current wave moving in the negative x direction.

In a similar manner, from a consideration of (56) and (57) we may write:

$$E_{rs}^+(x,p)=E_{rs}^0(p)e^{-a_2x}/2 \quad r=2,3,\ldots n \tag{108}$$

and

$$I_{rs}^+(x,p)=E_{rs}^0(p)e^{-a_2x}/2 \quad r=2,3,\ldots n \tag{109}$$

Since by symmetry, the negative waves behave in the same manner as the positive waves, we shall restrict our attention to the latter.

A. APPLICATION OF CONSTANT ELECTROMOTIVE FORCES

1. *The Voltage Waves*

Let us consider the application of n constant electromotive forces to the various conductors at $x=0$ and $t=0$, and let it be required to determine the magnitude of the resultant waves of voltage which result from the application of these electromotive forces. Let the magnitudes of the constant electromotive forces be given by the elements of the matrix:

$$(e^0)=(e_r) \qquad r=1, 2, \ldots n \tag{82}$$

Now we have:

$$(e^0)_s=[A]^{-1}(e^0) \tag{83}$$

From (36) it follows that:

$$E_{rs}{}^0 = e_{rs}{}^0 \qquad r=1, 2, 3, \ldots n \tag{110}$$

since the e_t terms are constants with respect to time. We must now obtain the inverse transform of the term e^{-ax}, where:

$$a=[(Lp+R)(Cp+G)]^{1/2} \tag{111}$$

This inverse transform is given in reference 7, table II, and in our notation we have:

$$e^{-ax} \div \begin{cases} 0 & t<x/v \\ e^{-rx/v}+\dfrac{sx}{v}\displaystyle\int_{x/v}^{t}\dfrac{e^{-ru}I_1\left(s\sqrt{u^2-x^2/v^2}\right)du}{\sqrt{u^2-x^2/v^2}} & t>x/v \end{cases} \tag{112}$$

where:

$$r=(R/L+G/C)/2 \tag{113}$$

$$s=(R/L-G/C)/2 \tag{114}$$

$$v=(LC)^{-1/2} \tag{115}$$

where $I_1(y)$ is the modified Bessel function of the first order. If we introduce the notation:

$$B_1(x, t) \div e^{-a_1x} \tag{116}$$

and

$$B_2(x, t) \div e^{-a_2x} \tag{117}$$

Then we have the set of equations:

$$\left.\begin{array}{l} e_{1s}{}^+=B_1(x, t)e_{1s}{}^0/2 \\ e_{rs}{}^+=B_2(x, t)e_{rs}{}^0/2 \cdots\cdots\cdots\cdots\cdots\cdots \end{array}\right\} \tag{118}$$

Defining the square matrix $[B]$ by the equation:

$$[B]=\left\|\begin{matrix} B_1 & 0 \ldots\ldots\ldots\ldots & 0 \\ 0 & B_2 \ldots\ldots\ldots\ldots & 0 \\ \cdots & \cdots\cdots\cdots\cdots\cdots & \cdots \\ 0 & 0 \ldots\ldots\ldots\ldots & B_2 \end{matrix}\right\| \tag{119}$$

then we may write the set (118) in the form:

$$(e^+)_s=\frac{1}{2}[B](e^0)_s \tag{120}$$

Or, by using (83) and premultiplying (120) by $[A]$ we have:

$$(e^+)=\frac{1}{2}[A][B][A]^{-1}(e^0) \tag{121}$$

This equation gives explicitly the values of the actual forward waves in terms of the constant applied electromotive forces at $x=0$.

2. *The Velocity of Propagation*

From the form of the expression 112 it is seen that the positive waves are composed of component waves having *two* velocities of propagation v_1 and v_2 given by the equations:

$$v_1=[L_0+(n-1)L][C_0+(n-1)C]^{-1/2} \tag{122}$$

and

$$v_2=[(L_0-L)(C_0-C)]^{-1/2} \tag{123}$$

In the case with dissipation, there is penetration of current into the line and hence the term L_0 does not have the value given by (68) but one intermediate between (68) and (5) depending on the transient skin effect. The velocities v_1 and v_2 are, therefore, less than the velocity of light and differ from each other.

3. *The Current Waves*

To obtain the positive current waves, we must consider the inverse transforms of (106) and (109). These inverse transforms depend on the inverse transform of an expression of the form: e^{-ax}/Z_0 where a has the value given by (111) and Z_0 is given by:

$$Z_0=[(Lp+R)/(Cp+G)]^{1/2} \tag{124}$$

From reference 7, table II we obtain:

$$e^{-ax}/Z_0 \div \begin{cases} 0 & t<x/v \\ \dfrac{e^{-rx/v}}{Z_0}+\dfrac{1}{k}\displaystyle\int_{x/v}^{t}e^{-ru}\left[\dfrac{su}{z}I_1(sz)-sI_0(sz)\right]du & t>x/v \end{cases} \tag{125}$$

where r, s, and v have the values given by (113) and (115) and we have:

$$k=(L/C)^{1/2} \tag{126}$$

$$z=(u^2-x^2/v^2)^{1/2} \tag{127}$$

Now if we introduce the notation:

$$H_1(x, t) \div e^{-ax_1}/Z_{01} \tag{128}$$

$$H_2(x, t) \div e^{-ax_2}/Z_{02} \tag{129}$$

then, in view of (106), (109), and (110), we may write equations 130.

$$\left.\begin{array}{l} i_{1s}{}^+=\dfrac{1}{2}H_1(x, t)e_{1s}{}^0 \\ i_{2s}{}^+=\dfrac{1}{2}H_2(x, t)e_{2s}{}^0 \\ \cdots\cdots\cdots\cdots\cdots\cdots \\ i_{ns}{}^+=\dfrac{1}{2}H_2(x, t)e_{ns}{}^0 \end{array}\right\} \tag{130}$$

If we introduce the square matrix $[H]$ defined by:

$$[H]=\left\|\begin{matrix} H_1 & 0 & 0 \ldots\ldots\ldots & 0 \\ 0 & H_2 & 0 \ldots\ldots\ldots & 0 \\ \cdots & \cdots & \cdots\cdots\cdots\cdots & \cdots \\ 0 & 0 & 0 \ldots\ldots\ldots & H_2 \end{matrix}\right\| \tag{131}$$

the set of equations 130 may then be written concisely in the form:

$$(i^+)=\frac{1}{2}[A][H][A]^{-1}(e^0) \tag{132}$$

This equation gives explicitly the values of the various forward waves of current in the n conductors in terms of the constant applied electromotive forces at $x=0$. From (125) it is seen that the current waves are composed of two sets of waves having the velocities given by (122).

B. THE APPLICATION OF VARIABLE ELECTROMOTIVE FORCES

In the above section, the method of computing the voltage and current waves resulting from the application of constant electromotive forces at $x=0$ and $t=0$ was given. If the applied electromotive forces are variable, with respect to time, the procedure must be modified.

The calculation of the effect produced by the application of variable electromotive forces is most easily carried out by the use of the Faltung theorem (105). To do this, we make use of the inverse transform (reference 7, table II)

$$pe^{-ax} \div \begin{cases} 0 & t<x/v \\ \delta(t-x/v)e^{-rx/v}+\dfrac{sx}{vz}e^{-rt}I_1(sz) & t>x/v \end{cases} \tag{134}$$

where a, r, s, v, and z are given by (111), (113), (114), (115), and (127) respectively and $\delta(t)$ has the property:

$$\int_{-\infty}^{+\infty}F(t)\delta(t-a)dt=F(a) \tag{135}$$

where $F(t)$ is an arbitrary function of t. We may also use the transform (136).

Linear Transformations in Three-Phase Circuits

LOUIS A. PIPES
ASSOCIATE AIEE

Synopsis: A general method of finding linear transformations to eliminate the coupling between substitutive networks is developed. The method is compared with that of symmetrical components and modified symmetrical components and its practical applicability is discussed.

SINCE the introduction of substituted variables in the analysis of polyphase networks by Stockvis,[1] in 1914 and Fortescue[2] in 1918, there has been a great deal of interest in the use of linear substitutions in the analysis of unbalanced three-phase systems. The substituted variables have been of many different types. Fortescue's method of symmetrical components was followed by the method of direct and quadrature axis quantities of Park,[3] and by the "modified symmetrical components" of Clarke.[4]

In a recent paper by Kimbark,[5] another set of substituted variables which are related to symmetrical components and to modified symmetrical components was presented. In the discussion of Kimbark's paper by Boyajian, Helwith, and Stigant, the power of matrix algebra in linear transformations was demonstrated.

A study of the literature shows that the use of substituted variables is of advantage provided that the three-phase system under consideration has certain symmetry so that the derived systems are not coupled. It is the purpose of this paper to present a general method by which the appropriate linear transformation may be found so that the coupling between the substitutive networks is eliminated.

I. Three-Phase Network With Grounded Neutral

To fix the ideas in question, consider an apparatus with four terminals as shown in figure 1. Three of the terminals are to be connected to the lines of a three-phase source and the fourth to the grounded neutral of the system.

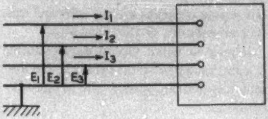

Figure 1

Let the complex line currents be I_1, I_2, and I_3, and the complex line-to-ground voltages E_1, E_2, E_3 be measured as shown in figure 1.

Paper 40-109, recommended by the AIEE committee on basic sciences, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted February 5, 1940; made available for preprinting May 17, 1940.

Louis A. Pipes is faculty instructor at Harvard University, Cambridge, Mass.

[1] For all numbered references, see list at end of paper.

$$pe^{-ax}/Z_0 \div \begin{cases} 0 & t<x/v \\ \frac{1}{k}e^{-rx/v}\delta(t-x/v)+\frac{1}{k}e^{-rt}\left[\frac{st}{z}I_1(sz)-sI_0(sz)\right] & t>x/v \end{cases} \tag{136}$$

where the various constants are defined in section *A* above. Let us now introduce the notation:

$$pe^{-a_1x}\div M_1(x,t) \tag{137}$$

$$pe^{-a_2x}\div M_2(x,t) \tag{138}$$

and introducing the square matrix:

$$[M(x,t)]=\left\|\begin{matrix} M_1(x,t) & 0\ldots\ldots.0 & \\ 0 & M_2(x,t)\ldots.0 & \\ \cdots & \cdots & \cdots \\ 0 & 0 & M_2(x,t)\end{matrix}\right\| \tag{139}$$

then it is easy to show by an application of (105) that the positive waves of voltage produced by the application of variable electromotive forces at $x=0$ and $t=0$ that are the elements of the matrix 82 are given explicitly by:

$$(e^+)=\frac{1}{2}\int_0^t [A][M(x,u)][A]^{-1}(e^0(t-u))du \tag{140}$$

In a similar manner, if we introduce the notation:

$$pe^{-a_1x}/Z_{01}\div N_1(x,t) \tag{141}$$

$$pe^{-a_2x}/Z_{02}\div N_2(x,t) \tag{142}$$

and the square matrix:

$$[N(x,t)]=\left\|\begin{matrix} N_1(x,t) & 0 & 0\ldots..0 \\ 0 & N_2(x,t) & 0\ldots..0 \\ \cdots & \cdots & \cdots \\ 0 & 0 & 0\ldots N_2(x,t)\end{matrix}\right\| \tag{143}$$

we have explicitly:

$$(i^+)=\frac{1}{2}\int_0^t [A][N(x,u)][A]^{-1}(e^0(t-u))du \tag{144}$$

an equation giving the various traveling waves of current produced by the application of the variable electromotive forces on the several lines.

VII. Conclusion

By the application of a symmetrical-component transformation and a Laplacian transformation to the canonical equations of the completely transposed *n*-wire transmission line, formal expressions have been obtained for the current and voltage waves on the system initiated by the application of arbitrary electromotive forces on the conductors at an arbitrary point on the lines.

The expressions obtained are simple and lend themselves readily to numerical computation. The simplicity of the analysis when matrix algebra and the Laplacian transformation are employed may be noted. It is hoped that the solution of this important technical problem by these methods will recommend them for the solution of similar problems whose difficulty may be termed "mechanical" rather than mathematical.

Then, by Kirchhoff's laws we may write the three voltage equations:

$$\left.\begin{aligned}E_1&=Z_{11}I_1+Z_{12}I_2+Z_{13}I_3\\E_2&=Z_{21}I_1+Z_{22}I_2+Z_{23}I_3\\E_3&=Z_{31}I_1+Z_{32}I_2+Z_{33}I_3\end{aligned}\right\}\qquad(1)$$

The complex numbers Z_{ij} are the self- and mutual impedances of the apparatus, and may be determined by measurement. The set of equations, (1), may be written concisely in the matrix form:

$$(E)=[Z](I) \qquad (2)$$

Where (E) is a column matrix whose elements are the voltages E_1, E_2, E_3, (I) is a column matrix whose elements are the line currents, and $[Z]$ is a square matrix whose elements are the self- and mutual impedances of the apparatus.

It may be noted that if the apparatus is a stationary bilateral network, the mutual impedances satisfy the reciprocity relations:

$$Z_{ij}=Z_{ji} \qquad (3)$$

and hence the impedance matrix, $[Z]$, satisfies the equation:

$$[Z]=[Z]' \qquad (4)$$

where $[Z]'$ is the transpose of the impedance matrix, $[Z]$.

In this case, the matrix $[Z]$ contains at most only six distinct coefficients. If the network is completely symmetrical, that is, the three phase impedances are equal and the six mutual impedances are also equal, then the coefficients merge into two in number, and we may write the impedance matrix in the form:

$$[Z]=\begin{Vmatrix}Z_0 & Z & Z\\ Z & Z_0 & Z\\ Z & Z & Z_0\end{Vmatrix} \qquad (5)$$

In the case of symmetrical rotating machines, the impedance matrix takes the form:

$$[Z]=\begin{Vmatrix}Z_0 & Z & Z_1\\ Z_1 & Z_0 & Z\\ Z & Z_1 & Z_0\end{Vmatrix} \qquad (6)$$

and is not symmetrical.

In the general three-phase problem it is required to determine the currents in the system when the elements of the impedance matrix and the voltages are known. This may always be done since $[Z]$ is a nonsingular matrix and has an inverse.

If we premultiply the equation 2 by $[Z]^{-1}$, the inverse of $[Z]$, we have:

$$(I)=[Z]^{-1}(E) \qquad (7)$$

an explicit solution for the currents.

The matrix $[Z]^{-1}$ has the value:

$$[Z]^{-1}=\frac{1}{D}\begin{Vmatrix}(Z_{22}Z_{33}-Z_{23}Z_{32}) & (Z_{32}Z_{13}-Z_{12}Z_{33}) & (Z_{12}Z_{23}-Z_{13}Z_{22})\\ (Z_{23}Z_{31}-Z_{21}Z_{33}) & (Z_{11}Z_{33}-Z_{13}Z_{31}) & (Z_{13}Z_{21}-Z_{11}Z_{23})\\ (Z_{21}Z_{32}-Z_{22}Z_{31}) & (Z_{12}Z_{31}-Z_{11}Z_{32}) & (Z_{11}Z_{22}-Z_{12}Z_{21})\end{Vmatrix} \qquad (8)$$

where D is the determinant:

$$D=\begin{vmatrix}Z_{11} & Z_{12} & Z_{13}\\ Z_{21} & Z_{22} & Z_{23}\\ Z_{31} & Z_{32} & Z_{33}\end{vmatrix} \qquad (9)$$

It is thus possible, by the use of the matrix $[Z]^{-1}$ in equation 7, to solve immediately for the currents I_1, I_2, and I_3 in the general case. This procedure, in general, is quite laborious and it is natural to ask if there exists an alternative procedure that will effect the solution more simply.

II. The General Linear Transformation

The general theory of linear transformations will now be presented and it will be apparent that the methods of Fortescue, Clarke, Kimbark, etc., are special cases of a general linear transformation. To fix the general method, the equations for the general three-phase network with grounded neutral will be considered.

Let the current and voltage matrices (I) and (E) be related to transformed current and voltage matrices $(I)_t$ and $(E)_t$ by the following matrix equations.

$$[B]^{-1}(I)=(I)_t \qquad (10)$$

$$[A](E)=(E)_t \qquad (11)$$

Where the matrix $(I)_t$ is a column matrix whose elements I_{1t}, I_{2t}, I_{3t} are the transformed currents of the currents I_1, I_2, I_3 with respect to the linear transformation (10). $[B]^{-1}$ is a nonsingular matrix whose elements are complex numbers. In a similar manner, the matrix $(E)_t$ is a column matrix whose elements E_{1t}, E_{2t}, E_{3t} are the transformed voltages of the voltages E_1, E_2, E_3, with respect to the linear transformation (11). $[A]$ is a nonsingular matrix whose elements are complex numbers.

Substituting these values of (I) and (E) from (10) and (11) into equation 2 one obtains:

$$[A][Z][B](I)_t=(E)_t \qquad (12)$$

Now if we let:

$$[Z]_t=[A][Z][B] \qquad (13)$$

then we can write equation 12 in the form:

$$[Z]_t(I)_t=(E)_t \qquad (14)$$

and we have an equation of the same form as (2) in the transformed voltages and currents.

If we let,

$$[A]=\begin{Vmatrix}A_{11} & A_{12} & A_{13}\\ A_{21} & A_{22} & A_{23}\\ A_{31} & A_{32} & A_{33}\end{Vmatrix} \qquad (15)$$

$$[B]=\begin{Vmatrix}B_{11} & B_{12} & B_{13}\\ B_{21} & B_{22} & B_{23}\\ B_{31} & B_{32} & B_{33}\end{Vmatrix} \qquad (16)$$

$$[Z]=\begin{Vmatrix}Z_{11t} & Z_{12t} & Z_{13t}\\ Z_{21t} & Z_{22t} & Z_{23t}\\ Z_{31t} & Z_{32t} & Z_{33t}\end{Vmatrix} \qquad (17)$$

then, the general element Z_{mnt} of the matrix $[Z]_t$ is given by:

$$Z_{mnt}=\sum_{r=1}^{r=3}\sum_{k=1}^{k=3}A_{mk}Z_{kr}B_{rn} \qquad (18)$$

as may be seen by direct matrix multiplication.

The whole point of introducing the linear transformations (10) and (11) is to choose the elements of the matrices $[A]$ and $[B]$ so that the matrix $[Z]_t$ will be simpler than the original matrix $[Z]$. If the elements of $[A]$ and $[B]$ are so chosen that the matrix $[Z]_t$ has the diagonal form:

$$[Z]_t=\begin{Vmatrix}Z_{11t} & 0 & 0\\ 0 & Z_{22t} & 0\\ 0 & 0 & Z_{33t}\end{Vmatrix} \qquad (19)$$

then the matrix equation 14 reduces to the set of three independent equations:

$$\left.\begin{aligned}Z_{11t}I_{1t}&=E_{1t}\\Z_{22t}I_{2t}&=E_{2t}\\Z_{33t}I_{3t}&=E_{3t}\end{aligned}\right\}\qquad(20)$$

and we may solve for the transformed currents most simply. The actual currents of the system are obtained by:

$$(I)=[B](I)_t \qquad (21)$$

Before discussing the general question of reducing the matrix $[Z]$ to the diagonal form (19) by the transformation (13), it is well to consider the special types of transformations which have been used in practice in the light of the general theory.

III. Symmetrical Components

The special type of linear transformation which is used in the theory of symmetrical components is effected by a nonsingular, symmetric matrix $[S]$ defined by the equation:

$$[S]=\begin{Vmatrix}1 & 1 & 1\\ 1 & a^2 & a\\ 1 & a & a^2\end{Vmatrix} \qquad (22)$$

where,

$$a=e^{2\pi j/3} \qquad (23)$$

From the definition of $[S]$ it is easy to show that $[S]$ has the following properties:

$$[S]^{-1}=\frac{1}{3}[\text{conj } S]=\frac{1}{3}[\overline{S}] \tag{24}$$

where [conj S] is the conjugate of $[S]$.

$$[S]'=[S] \tag{25}$$

where $[S]'$ is the transpose of $[S]$.

In the theory of symmetrical components, the equations:

$$[S]^{-1}(I)=(I)_s \tag{26}$$

$$[S]^{-1}(E)=(E)_s \tag{27}$$

replace the equations 10 and 11. Where $(I)_s$ and $(E)_s$ are matrices whose elements are symmetrical components of current and voltage respectively. Comparing these two sets of equations, it may be seen that the matrix $[S]$ is related to the matrices $[A]$ and $[B]$ of the general transformation of section II by the equations:

$$[S]=[B] \tag{28}$$

$$[S]^{-1}=[A] \tag{29}$$

The transformed matrix (13) is now given by:

$$[Z]_s=[S]^{-1}[Z][S]=\frac{1}{3}[\overline{S}][Z][S] \tag{30}$$

By direct matrix multiplication, one obtains:

$$[Z]_s=\begin{Vmatrix} Z_{11s} & Z_{12s} & Z_{13s} \\ Z_{21s} & Z_{22s} & Z_{23s} \\ Z_{31s} & Z_{32s} & Z_{33s} \end{Vmatrix}\frac{1}{3} \tag{31}$$

where:

$$\left.\begin{aligned}
Z_{11s}&=Z_{11}+Z_{21}+Z_{31}+Z_{12}+Z_{22}+\\ &\quad Z_{32}+Z_{13}+Z_{23}+Z_{33}\\
Z_{12s}&=Z_{11}+Z_{21}+Z_{31}+a^2Z_{12}+a^2Z_{22}+\\ &\quad a^2Z_{32}+a(Z_{13}+Z_{23}+Z_{33})Z_{33}\\
Z_{13s}&=Z_{11}+Z_{21}+Z_{31}+a(Z_{12}+Z_{22}+\\ &\quad Z_{32})+a^2(Z_{13}+Z_{23}+Z_{33})\\
Z_{21s}&=Z_{11}+Z_{12}+Z_{13}+a(Z_{21}+Z_{22}+\\ &\quad Z_{23})+a^2(Z_{31}+Z_{32}+Z_{33})\\
Z_{22s}&=Z_{11}+Z_{22}+Z_{33}+a(Z_{21}+Z_{32}+\\ &\quad Z_{13})+a^2(Z_{31}+Z_{12}+Z_{23})\\
Z_{23s}&=Z_{11}+Z_{22}+Z_{33}+a(Z_{31}+Z_{12}+\\ &\quad Z_{23})+a^2(Z_{21}+Z_{32}+Z_{13})\\
Z_{31s}&=Z_{11}+Z_{12}+Z_{13}+a(Z_{31}+Z_{32}+\\ &\quad Z_{33})+a^2(Z_{21}+Z_{22}+Z_{23})\\
Z_{32s}&=Z_{11}+Z_{22}+Z_{33}+a(Z_{31}+Z_{12}+\\ &\quad Z_{13})+a^2(Z_{21}+Z_{12}+Z_{33})\\
Z_{33s}&=Z_{11}+Z_{22}+Z_{33}+a(Z_{21}+Z_{12}+\\ &\quad Z_{23})+a^2(Z_{21}+Z_{32}+Z_{13})
\end{aligned}\right\} \tag{32}$$

It is thus seen that if the matrix $[Z]$ is the general matrix, the transformed impedance matrix $[Z]_s$ is far more complicated than the original one.

Simplification in Cases of Symmetry

From the general form of (31) it is evident that the method of symmetrical components effects no simplification if the system exhibits no symmetry. However, if the original matrix $[Z]$ has the perfectly symmetrical form:

$$[Z]=\begin{Vmatrix} Z_0 & Z & Z \\ Z & Z_0 & Z \\ Z & Z & Z_0 \end{Vmatrix} \tag{33}$$

then $[Z]_s$ has the diagonal form:

$$[Z]_s=\begin{Vmatrix} (Z_0+2Z) & 0 & 0 \\ 0 & (Z_0-Z) & 0 \\ 0 & 0 & (Z_0-Z) \end{Vmatrix} \tag{34}$$

and the several sequence voltages and currents are independent. Since most balanced polyphase systems have this type of symmetry, this accounts for the great simplification introduced in the analysis of these systems by the method of symmetrical components.

Another important type of matrix that may be diagonalized by a transformation to symmetrical components is the matrix:

$$[Z]=\begin{Vmatrix} Z_0 & Z_1 & Z_2 \\ Z_2 & Z_0 & Z_1 \\ Z_1 & Z_2 & Z_0 \end{Vmatrix} \tag{35}$$

This case occurs in the theory of three phase synchronous and induction machines with smooth air gaps. In this case, the matrix $[Z]_s$ has the form:

$$[Z]_s=\begin{Vmatrix} (Z_0+Z_1+Z_2) & 0 & 0 \\ 0 & (Z_0+a^2Z_1+aZ_2) & 0 \\ 0 & 0 & (Z_0+aZ_1+a^2Z_2) \end{Vmatrix} \tag{36}$$

and a simplification is introduced by the method of symmetrical components.

IV. Modified Symmetrical Components

Clarke,[4] defines another set of substituted variables which she has named "modified symmetrical components". They may be obtained from the general transformations (10) and (11) by choosing the matrix $[B]^{-1}$ to be:

$$[B]^{-1}=\begin{Vmatrix} 1/3 & 1/3 & 1/3 \\ 2/3 & -1/3 & -1/3 \\ 0 & 1/2 & -1/2 \end{Vmatrix} \tag{37}$$

$$[A]=[B]^{-1} \tag{38}$$

In this case the transformed currents and voltages have the form:

$$(I)_t=\begin{Vmatrix} I_0 \\ I_\alpha \\ I_\beta \end{Vmatrix} \tag{39}$$

$$(E)_t=\begin{Vmatrix} E_0 \\ E_\alpha \\ E_\beta \end{Vmatrix} \tag{40}$$

The matrix $[A]$ has the inverse:

$$[A]^{-1}=\begin{Vmatrix} 1 & 1 & 0 \\ 1 & -1/2 & \sqrt{3}/2 \\ 1 & -1/2 & -\sqrt{3}/3 \end{Vmatrix}=[B] \tag{41}$$

The transformed impedance matrix is given by (13) and by matrix multiplication we obtain:

$$[Z]_t=\begin{Vmatrix} Z_{11t} & Z_{12t} & Z_{13t} \\ Z_{21t} & Z_{22t} & Z_{23t} \\ Z_{31t} & Z_{32t} & Z_{33t} \end{Vmatrix} \tag{42}$$

where for this case the elements of $[Z]_t$ are found by direct multiplication to be:

$$\left.\begin{aligned}
Z_{11t}&={}^1/_3(Z_{11}+Z_{21}+Z_{31}+Z_{12}+Z_{22}+\\ &\quad Z_{32}+Z_{13}+Z_{23}+Z_{33})\\
Z_{12t}&={}^1/_3(Z_{11}+Z_{21}+Z_{31})-{}^1/_6(Z_{12}+\\ &\quad Z_{22}+Z_{32})-{}^1/_6(Z_{13}+Z_{23}+Z_{33})\\
Z_{13t}&=\frac{1}{2\sqrt{3}}(Z_{12}+Z_{22}+Z_{32})-\\ &\quad \frac{1}{2\sqrt{3}}(Z_{13}+Z_{23}+Z_{33})\\
Z_{21t}&={}^2/_3(Z_{11}+Z_{12}+Z_{13})-{}^1/_3(Z_{21}+\\ &\quad Z_{31}+Z_{22}+Z_{32}+Z_{23}+Z_{33})\\
Z_{22t}&=\left(\frac{2}{3}Z_{11}-\frac{1}{3}Z_{21}-\frac{1}{3}Z_{31}\right)-\\ &\quad \frac{1}{2}\left(\frac{2}{3}Z_{12}-\frac{1}{3}Z_{22}-\frac{1}{3}Z_{32}\right)-\\ &\quad \frac{1}{2}\left(\frac{2}{3}Z_{13}-\frac{1}{3}Z_{23}-\frac{1}{3}Z_{33}\right)\\
Z_{23t}&=\frac{\sqrt{3}}{2}\left(\frac{2}{3}Z_{12}-\frac{1}{3}Z_{22}-\frac{1}{3}Z_{32}\right)-\\ &\quad \frac{\sqrt{3}}{2}\left(\frac{2}{3}Z_{13}-\frac{1}{3}Z_{23}-\frac{1}{3}Z_{33}\right)\\
Z_{31t}&={}^1/_2(Z_{21}+Z_{22}+Z_{23}-Z_{31}-\\ &\quad Z_{32}-Z_{33})\\
Z_{32t}&={}^1/_2(Z_{21}-Z_{31})+\\ &\quad {}^1/_4(Z_{32}-Z_{22}+Z_{33}-Z_{23})\\
Z_{33t}&=\frac{\sqrt{3}}{4}(Z_{22}-Z_{32}-Z_{23}+Z_{33})
\end{aligned}\right\} \tag{43}$$

Simplification in the Case of Symmetry

If there is symmetry about phase 1, that is, if the following relations are satisfied:

$$Z_{22}=Z_{33},\ Z_{12}=Z_{21}=Z_{13}=Z_{31},\ Z_{23}=Z_{32} \tag{44}$$

then the transformed matrix reduces to:

$$[Z]_t=\begin{Vmatrix} Z_{11t} & Z_{12t} & 0 \\ Z_{21t} & Z_{22t} & 0 \\ 0 & 0 & Z_{33t} \end{Vmatrix} \tag{45}$$

the values of the elements of (45) are given by the equations 43 provided use is made of the symmetry conditions (44).

It is thus seen that if there is symmetry about phase 1 the transformed matrix is simplified but not diagonalized. The coupling between the transformed or sequence circuits is reduced.

V. Two-Phase Co-ordinates

Kimbark[5] has introduced a slightly different linear transformation than that used by Clarke and calls the transformed voltages and currents "two-phase co-ordinates". This transformation is effected by giving the following values to the elements of the matrices $[A]$ and $[B]$ of the general linear transformation (10) and (11).

$$[A]=\begin{Vmatrix} {}^{2}/_{3} & -{}^{1}/_{3} & -{}^{1}/_{3} \\ 0 & -1/\sqrt{3} & 1/\sqrt{3} \\ {}^{1}/_{3} & {}^{1}/_{3} & {}^{1}/_{3} \end{Vmatrix} \qquad (46)$$

$$[B]^{-1}=\begin{Vmatrix} {}^{2}/_{3} & -{}^{1}/_{3} & -{}^{1}/_{3} \\ 0 & -1/\sqrt{3} & 1/\sqrt{3} \\ {}^{2}/_{3} & {}^{2}/_{3} & {}^{2}/_{3} \end{Vmatrix} \qquad (47)$$

The transformed currents and voltages are given by:

$$(I)_t=\begin{Vmatrix} I_x \\ I_y \\ I_z \end{Vmatrix} \qquad (48)$$

$$(E)_t=\begin{Vmatrix} E_x \\ E_y \\ E_z \end{Vmatrix} \qquad (49)$$

The transformation matrices have the inverses:

$$[A]^{-1}=\begin{Vmatrix} 1 & 0 & 1 \\ -\frac{1}{2} & \frac{-\sqrt{3}}{2} & 1 \\ -\frac{1}{2} & \frac{\sqrt{3}}{2} & 1 \end{Vmatrix} \qquad (50)$$

$$[B]=\begin{Vmatrix} 1 & 0 & \frac{1}{2} \\ -\frac{1}{2} & \frac{-\sqrt{3}}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{\sqrt{3}}{2} & \frac{1}{2} \end{Vmatrix} \qquad (51)$$

By direct multiplication, the transformed impedance matrix is found to be:

$$[Z]_t=\begin{Vmatrix} Z_{11t} & Z_{12t} & Z_{13t} \\ Z_{21t} & Z_{22t} & Z_{23t} \\ Z_{31t} & Z_{32t} & Z_{33t} \end{Vmatrix} \qquad (52)$$

where in this case the elements of the transformed matrix are given by:

$$\left.\begin{aligned}
Z_{11t}&=\frac{1}{6}(4Z_{11}-2Z_{12}-2Z_{13}-2Z_{21}+ \\ &\qquad Z_{22}+Z_{23}-2Z_{31}+Z_{32}+Z_{33}) \\
Z_{12t}&=\frac{1}{2\sqrt{3}}(2Z_{13}-2Z_{12}+Z_{22}-Z_{23}+ \\ &\qquad Z_{32}-Z_{33}) \\
Z_{13t}&=\frac{1}{6}(2Z_{11}+2Z_{12}+2Z_{13}-Z_{21}- \\ &\qquad Z_{22}-Z_{23}-Z_{31}-Z_{32}-Z_{33}) \\
Z_{21t}&=\frac{1}{2\sqrt{3}}(Z_{22}-2Z_{21}+Z_{23}+2Z_{31}- \\ &\qquad Z_{32}-Z_{33}) \\
Z_{22t}&=Z_{22}-Z_{23}-Z_{32}+Z_{33} \\
Z_{23t}&=\frac{1}{2\sqrt{3}}(Z_{31}+Z_{32}+Z_{33}-Z_{21}- \\ &\qquad Z_{22}-Z_{23}) \\
Z_{31t}&=\frac{1}{6}(2Z_{11}-Z_{12}-Z_{13}+2Z_{21}-Z_{22}- \\ &\qquad Z_{23}+2Z_{31}-Z_{32}-Z_{33}) \\
Z_{32t}&=\frac{1}{2\sqrt{3}}(Z_{13}-Z_{12}-Z_{22}+Z_{23}- \\ &\qquad Z_{32}+Z_{33}) \\
Z_{33t}&=\frac{1}{6}(Z_{11}+Z_{12}+Z_{13}+Z_{21}+Z_{22}+ \\ &\qquad Z_{23}+Z_{31}+Z_{32}+Z_{33})
\end{aligned}\right\} \qquad (53)$$

This is the general form of the transformed matrix. In the special case of symmetry about phase 1, we have:

$$Z_{22}=Z_{33},\ Z_{12}=Z_{21}=Z_{13}=Z_{31},\ Z_{23}=Z_{32} \qquad (54)$$

In this symmetrical case, the transformed impedance matrix reduces to:

$$[Z]_t=\begin{Vmatrix} \frac{1}{3}(2Z_{11}-4Z_{12}+Z_{22}+Z_{23}) & 0 & \frac{1}{6}(Z_{11}+Z_{12}-Z_{22}-Z_{23}) \\ 0 & (Z_{22}-Z_{23}) & 0 \\ \frac{1}{3}(Z_{11}+Z_{12}-Z_{22}-Z_{23}) & 0 & \frac{1}{3}\left(\frac{1}{2}Z_{11}+2Z_{12}+Z_{22}+Z_{23}\right) \end{Vmatrix} \qquad (55)$$

We note that as in the case of modified symmetrical components the coupling is reduced by this linear transformation in the case of symmetry about phase 1.

VI. The Reduction of a Square Matrix to the Diagonal Form

The above brief discussion of the various linear transformations which have been used in the analysis of networks reveals the fact that these transformations are introduced in order that the transformed matrix will have a simpler form than the original matrix. In case that the transformed matrix has the diagonal form, then the various transformed voltages and currents are related to one another in a most simple manner.

The reduction of given matrices to the diagonal form is one of the fundamental problems of matrix algebra. In order to understand the problem it is essential to know what is meant by equivalent matrices in a certain number field, F.

EQUIVALENT MATRICES IN A FIELD

The matrix $[Z]$ whose elements are complex numbers is equivalent in the field of complex numbers to the matrix $[Z]_t$ if nonsingular matrices $[A]$ and $[B]$ exist so that:

$$[Z]_t=[A][Z][B] \qquad (13)$$

where the elements of $[A]$, $[Z]$, $[B]$, and therefore of $[Z]_t$ all belong to the field of complex numbers.

For a given matrix $[Z]$ in the complex number field, F, the problem is to discover non-singular matrices $[A]$ and $[B]$ which will make the equivalent matrix $[Z]_t$ as simple as possible, a diagonal form being the most desirable.

H. J. S. Smith[6] has demonstrated that given a square matrix $[Z]$ of n rows and columns, there exists a diagonal matrix:

$$[A][Z][B]=\begin{Vmatrix} a_1 & 0 & 0 & 0 \ldots\ldots\ldots \\ 0 & a_2 & 0 & 0 \ldots\ldots\ldots \\ \ldots & \ldots & \ldots & \ldots\ldots\ldots\ldots \\ 0 & 0 & 0 & 0\ a_r \ldots\ldots \\ 0 & 0 & 0 & 0 \ldots\ldots 0 \end{Vmatrix} \qquad (56)$$

that has r nonzero elements a_i isolated in the diagonal, and that is equivalent to $[Z]$ in the complex number field, F. The set of r numbers a_i are rational functions of the elements Z_{ij} of Z.

The proof of this theorem consists of operating successively on $[Z]$ with matrices $[A]_i$ and $[B]_i$ so chosen that the matrices $[A]_1[Z][B]_1$, $[A]_2[A]_1[Z][B]_1\times[B]_2$, etc., assume more and more the diagonal form.

FUNDAMENTAL OPERATIONS

The operations which will be used to diagonalize the matrix $[Z]$ will be of the following fundamental types:

(*a*). *Interchange of Rows and Columns*

Consider the identity:

$$\begin{Vmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{Vmatrix} \begin{Vmatrix} Z_{11} & Z_{12} & Z_{13} \\ Z_{21} & Z_{22} & Z_{23} \\ Z_{31} & Z_{32} & Z_{33} \end{Vmatrix} = \begin{Vmatrix} Z_{21} & Z_{22} & Z_{23} \\ Z_{11} & Z_{12} & Z_{13} \\ Z_{31} & Z_{32} & Z_{33} \end{Vmatrix} \qquad (57)$$

This shows that the effect of premultiplying $[Z]$ by a unit matrix in which the first two rows have been interchanged is to interchange the same two rows in $[Z]$.

Let $U_{(ij)}$ denote the unit matrix in which the ith and jth rows have been interchanged without disturbing the remaining $(n-2)$ rows. By direct multiplication it may be shown that the effect of multiplying $[Z]$ by such a matrix will be:

$$\left.\begin{array}{l} U_{(ij)}[Z]\text{: interchanges row}_i\text{ and row}_j \\ [Z]U_{(ij)}\text{: interchanges column}_i\text{ and} \\ \qquad \text{column}_j \\ U_{(ij)}[Z]U_{(ij)}\text{: interchanges both rows} \\ \qquad \text{and columns } i,j \end{array}\right\} \qquad (58)$$

(*b*). *Linear Combinations of Rows or Columns*

If we consider the identity:

$$\begin{Vmatrix} 1 & 0 & 0 \\ 0 & 1 & k \\ 0 & 0 & 1 \end{Vmatrix} \begin{Vmatrix} Z_{11} & Z_{12} & Z_{13} \\ Z_{21} & Z_{22} & Z_{23} \\ Z_{31} & Z_{32} & Z_{33} \end{Vmatrix} =$$

$$\begin{Vmatrix} Z_{11} & Z_{12} & Z_{13} \\ (Z_{21}+kZ_{31}) & (Z_{22}+kZ_{32}) & (Z_{23}+kZ_{33}) \\ Z_{31} & Z_{32} & Z_{33} \end{Vmatrix} \qquad (59)$$

we see that premultiplication of $[Z]$ by a unit matrix supplemented by an element k in the indicated position has the effect of giving the operation $\text{row}_2+k\ \text{row}_3$.

In general, let:

$$[H]=U+(k)_{ij} \quad (i\neq j) \qquad (60)$$

denote the unit matrix with an element k inserted in the (ij)th position. Then it can be seen that:

$$\left.\begin{array}{l}[H][Z]:\text{row}_i+k\ \text{row}_j\\ [Z][H]:\text{col}_j+k\ \text{col}_i\end{array}\right\}\qquad(61)$$

It may be noted that transformations of the type (a) and (b) involve pre- and postmultiplication by matrices whose determinants are equal to unity. Transformations of this type are unimodular transformations.

(c). *Multiplication of Rows or Columns*

In operations of type (b), the element k had been inserted in the diagonal of U where $k\neq-1$, then we would have:

$$[H]=U+(k)_{ii}\qquad(62)$$

$$H=1+k\qquad(63)$$

If

$$h=1+k\qquad(64)$$

the rules of operation for this matrix are:

$$\begin{array}{l}[H][Z]:h\ \text{row}_i\\ [Z][H]:h\ \text{col}_i\end{array}\qquad(65)$$

VII. Diagonalizing a Symmetric Matrix

As an example of the general procedure of section VI let the problem of reducing the impedance of a static three-phase system to the equivalent diagonal form be considered.

Static networks have the property that their impedance matrices are symmetrical, that is, $Z_{ij}=Z_{ji}$. The problem in this case is to reduce the matrix:

$$[Z]=\begin{Vmatrix}Z_{11}&Z_{12}&Z_{13}\\Z_{21}&Z_{22}&Z_{23}\\Z_{31}&Z_{32}&Z_{33}\end{Vmatrix}\qquad(66)$$

to the diagonal form by finding the proper transformation matrices $[A]$ and $[B]$.

As a first step in the procedure, let us write:

$$n_{ij}=Z_{ij}/Z_{11}\qquad(67)$$

since the elements of the $[Z]$ matrix are complex numbers, n_{ij} will, in general, be a complex number. In terms of the numbers n_{ij} we may write:

$$[Z]=Z_{11}\begin{Vmatrix}1&n_{12}&n_{13}\\n_{21}&n_{22}&n_{23}\\n_{31}&n_{32}&n_{33}\end{Vmatrix}\qquad(68)$$

It is evident that this matrix may be diagonalized by operations involving linear combinations of rows and columns as discussed in section VI part b.

We have as a first step:

$$\begin{Vmatrix}1&0&0\\-n_{12}&1&0\\0&0&1\end{Vmatrix}\begin{Vmatrix}1&n_{12}&n_{13}\\n_{12}&n_{22}&n_{23}\\n_{13}&n_{23}&n_{33}\end{Vmatrix}Z_{11}=$$

$$Z_{11}\begin{Vmatrix}1&n_{12}&n_{13}\\0&(n_{22}-n_{12}^2)&(n_{23}-n_{13}n_{12})\\n_{13}&n_{23}&n_{33}\end{Vmatrix}\qquad(69)$$

The next step is to premultiply this matrix by one that will remove the factor n_{13} in the first column. Then the resulting matrix is postmultiplied by matrices that will remove the factors n_{12} and n_{13} in the first row. These matrices may then be multiplied together in the proper order. At this stage we have:

$$Z_{11}\begin{Vmatrix}1&0&0\\-n_{12}&1&0\\-n_{13}&0&1\end{Vmatrix}\begin{Vmatrix}1&n_{12}&n_{13}\\n_{12}&n_{22}&n_{23}\\n_{13}&n_{23}&n_{33}\end{Vmatrix}\begin{Vmatrix}1&-n_{12}&-n_{13}\\0&1&0\\0&0&1\end{Vmatrix}=$$

$$Z_{11}\begin{Vmatrix}1&0&0\\0&(n_{22}-n_{12}^2)&(n_{23}-n_{13}n_{12})\\0&(n_{23}-n_{13}n_{12})&(n_{33}-n_{13}^2)\end{Vmatrix}\qquad(70)$$

Further diagonalizing may be accomplished in the same manner and we finally obtain:

$$[A][Z][B]=Z_{11}\begin{Vmatrix}1&0&0\\0&(n_{22}-n_{12}^2)&0\\0&0&[k(n_{23}-n_{13})+(n_{33}-n_{13}^2)]\end{Vmatrix}\qquad(71)$$

where:

$$[A]=\begin{Vmatrix}1&0&0\\-n_{12}&1&0\\-(kn_{12}+n_{13})&k&1\end{Vmatrix}\qquad(72)$$

$$[B]=\begin{Vmatrix}1&-n_{12}&-(kn_{12}+n_{13})\\0&1&k\\0&0&1\end{Vmatrix}\qquad(73)$$

$$k=(n_{12}n_{13}-n_{23})/(n_{22}-n_{12}^2)\qquad(74)$$

It may be noted that in this case, $[B]=[A]'$. The matrices $[A]$ and $[B]$ have the inverses:

$$[A]^{-1}=\begin{Vmatrix}1&0&0\\n_{12}&1&0\\n_{13}&-k&1\end{Vmatrix}\qquad(75)$$

$$[B]^{-1}=\begin{Vmatrix}1&n_{12}&n_{13}\\0&1&-k\\0&0&1\end{Vmatrix}\qquad(76)$$

Unlike the special choice of the matrices $[A]$ and $[B]$ used in the theory of symmetrical components and modified symmetrical components, the matrices required to diagonalize the general symmetric impedance matrix $[Z]$ contains elements that depend on the various elements of $[Z]$. This is unavoidable. However the numbers n_{ij} and k may be easily computed and the matrix under consideration diagonalized. It may be noted that the procedure of diagonalizing a given matrix is not unique but may be carried out in many ways.

The general procedure outlined in part VI is always applicable and advantage may be taken of the symmetry of the matrix under consideration.

VIII. Diagonalizing the General Unsymmetric Matrix

As a last example of the general procedure let the problem of diagonalizing the general unsymmetric impedance matrix of a three-phase system be considered. Specifically, the problem is to find matrices $[A]$ and $[B]$ that will reduce the general matrix:

$$[Z]=\begin{Vmatrix}Z_{11}&Z_{12}&Z_{13}\\Z_{21}&Z_{22}&Z_{23}\\Z_{31}&Z_{32}&Z_{33}\end{Vmatrix}\qquad Z_{ij}\neq Z_{ji}\qquad(77)$$

to the diagonal form. By the same method used in section VII, it may be shown that the matrices:

$$[A]=\begin{Vmatrix}1&0&0\\-n_{21}&1&0\\-(k_1n_{21}+n_{31})&k_1&1\end{Vmatrix}\qquad(78)$$

$$[B]=\begin{Vmatrix}1&-n_{12}&-(k_2n_{12}+n_{13})\\0&1&k_2\\0&0&1\end{Vmatrix}\qquad(79)$$

$$k_1=(n_{12}n_{31}-n_{32})/(n_{22}-n_{12}n_{21})\qquad(80)$$

$$k_2=(n_{21}n_{13}-n_{23})/(n_{22}-n_{12}n_{21})\qquad(81)$$

Diagonalize the matrix $[Z]$ in the form:

$$[A][Z][B]=Z_{11}\begin{Vmatrix}1&0&0\\0&(n_{22}-n_{12}n_{21})&0\\0&0&[k_1(n_{23}-n_{12}n_{13})+(n_{33}-n_{13}n_{31})]\end{Vmatrix}\qquad(82)$$

The complex numbers n_{ij} have the same significance that they have in section VII.

IX. Transformation of the Vector Volt-Ampere Input

The vector volt-ampere input P, in terms of the original voltages and currents of the system is defined by the equation:

$$P=(I)'(\text{conj }E)\qquad(83)$$

where $(I)'$ is the transpose of the current matrix (I) and (conj E) is the conjugate of the voltage matrix.

Substituting for (I) and (E) the values given in terms of $(I)_t$ and $(E)_t$ by the general transformation equations, (10) and (11), we have:

$$P=([B](I)_t)'[\text{conj }A]^{-1}(\text{conj }E)_t\qquad(84)$$

but by a fundamental theorem of matrix algebra we have:

$$([B](I)_t)'=(I)_t'[B]'\qquad(85)$$

Hence we have:

$$P=(I)_t'[B]'[\text{conj } A]^{-1}(\text{conj } E)_t \qquad (86)$$

Now, if:

$$[B]'=[\text{conj } A] \qquad (87)$$

then:

$$P=(I)_t'(\text{conj } E)_t=P_t \qquad (88)$$

and the vector volt-ampere input is invariant to the linear transformation. The relation (87) is not in general satisfied and the equation (86) gives the proper result in all cases.

X. Illustrative Example

Consider a three phase system whose impedance matrix has the value:

$$[Z]=\begin{Vmatrix}(4.84+j1.30) & (3.48+j2.00) & (1.81+j.846)\\ (8.95+j.945) & (9.98+j.690) & (2.97+j.416)\\ (15.05+j5.48) & (5.65+j5.65) & (5.36+j4.50)\end{Vmatrix} \qquad (89)$$

Let the voltage matrix of the system be:

$$(E)=\begin{Vmatrix}100\\ 80\;\underline{/100^\circ}\\ 70\;\underline{/200^\circ}\end{Vmatrix} \qquad (90)$$

Let it be required to determine the proper transformation that will diagonalize $[Z]$ and hence make the various sequence networks independent of one another. Let the resulting three phase currents of the system be determined.

From equations 78, 79, 80, 81, and 82, the following matrices are calculated.

$$[A]=\begin{Vmatrix}1 & 0 & 0\\ 1.8\;\underline{/171} & 1 & 0\\ 5.02\underline{/161^\circ 40'} & 1.345\underline{/-40^\circ 35'} & 1\end{Vmatrix} \qquad (91)$$

$$[B]=\begin{Vmatrix}1 & .8\underline{/195^\circ} & .552\underline{/187^\circ 10'}\\ 0 & 1 & .192\underline{/-14^\circ 42'}\\ 0 & 0 & 1\end{Vmatrix} \qquad (92)$$

The transformed impedance matrix is diagonalized by these two matrices and has the value:

$$5\underline{/15^\circ}\begin{Vmatrix}1 & 0 & 0\\ 0 & .754\underline{/44^\circ 52'} & 0\\ 0 & 0 & .758\underline{/-77^\circ 53'}\end{Vmatrix}=[Z_t] \qquad (93)$$

The transformed voltage matrix is given by (11) and has the value:

$$(E)_t=\begin{Vmatrix}100\\ 224\underline{/151^\circ 50'}\\ 536\underline{/155^\circ}\end{Vmatrix} \qquad (94)$$

In the transformed system, the sequence voltages and currents are independent because of the diagonal form of the impedance matrix. The matrix equation $[Z]_t(I)_t=(E)_t$ reduces in this case to the three scalar equations:

$$\left.\begin{matrix}(5\underline{/15^\circ})I_{1t}=100\\ (5\underline{/15^\circ})(.754\underline{/44^\circ 52'})I_{2t}=224\underline{/151^\circ 50'}\\ (5\underline{/15^\circ})(.758\underline{/-77^\circ 53'})I_{3t}=536\underline{/155^\circ}\end{matrix}\right\} \qquad (95)$$

These equations may be solved for the sequence currents by division and the transformed current matrix is found to be:

$$(I)_t=\begin{Vmatrix}20\underline{/-15^\circ}\\ 59.5\underline{/91^\circ 58'}\\ 141\underline{/217^\circ 53'}\end{Vmatrix} \qquad (96)$$

The phase currents are then obtained by the equation $(I)=[B](I)_t$ and we have:

$$(I)=\begin{Vmatrix}88.5\underline{/2^\circ 50'}\\ 55.7\underline{/119^\circ}\\ 141\underline{/217^\circ 53'}\end{Vmatrix} \qquad (97)$$

This example illustrates how a general unsymmetrical matrix may be diagonalized by the method of section VIII. As in the case of symmetrical components, the sequence networks are independent.

XI. Conclusion

The general method presented in this paper is a generalization of the method of symmetrical components, modified symmetrical components, etc., in that by its use the proper transformation matrix may be determined to make the various sequence currents and voltages of a general system independent. It therefore appears that by the use of this method a large class of problems that cannot be solved by the use of symmetrical components because of lack of symmetry may be solved in a manner very similar to that of symmetrical components.

High-Voltage D-C Point Discharges

E. C. STARR
MEMBER AIEE

Synopsis: D-c corona discharges from pointed and sharp-edged conductors have been found to give rise to severe radio interference on aircraft under certain precipitation conditions. Laboratory studies, employing a point-to-plane arrangement, have shown that these discharges are greatly influenced not only by voltage and polarity but also by the geometry of the points.

Three distinct types of positive and two of negative corona have been found. One of these types, that occurring on sharp, slender points, is essentially common to both polarities and is free from radio interference at all frequencies up to at least several megacycles. Those discharges common to rather bluntly-backed points extend out some distance from the electrodes and are made up, in general, of a steady ion-migration component plus a series, orderly or otherwise, of ionic bursts. The latter phenomena, through an impulse excitation mechanism, give rise to the radio interference.

A number of oscillograms were taken with the Duddell-type oscillograph showing the simultaneous current and radio-interference characteristics of the various types of point discharges. These oscillograms, taken with carefully constructed amplifiers, show the steady component of the discharge to be free from radio interference. Each impulsive burst, however, gives rise to a burst of radio output. Cathode-ray oscillograms show these current bursts to be typical double-exponential impulses of very steep wave front, and in general, of short duration. High resistance in the discharge circuit near the ionization point has a suppressing action on the impulses and greatly reduces the accompanying interference. Further reduction can be effected by the addition of inductance in the discharge circuit.

AN extensive investigation of precipitation-static interference phenomena in aircraft radio led to the conclusion that high-voltage corona discharges were

R_1—5,000–25,000 ohms
R_2—0.5 megohm
R_3—200 ohms
C_2—0.25 microfarad

responsible for the major part of this interference.[1,2,7] It was observed that these discharges were of a d-c nature and that they occurred from sharp points and edges in the vicinity of the extremities of all-metal airplanes. In an attempt to analyze the erratic character of the observed disturbances and to devise means for controlling the discharges, the investigation outlined in this paper was undertaken.

It was found that the familiar point-to-plane gap which has been used by other investigators[3] gave excellent results and that all of the different types of radio interference observed in actual flight could be produced by it under accurately controlled conditions in the laboratory. By obtaining a qualitative record on the Duddell oscillograph, it was possible to study the character of, and correlation between, the discharges and accompanying radio disturbances. The cathode-ray oscillograph indicated the true instantaneous characteristics of the discharges and made possible a thorough analysis of the basic mechanism.

Experimental Study

Early in the investigation, it was learned that the type of discharge obtained was dependent very largely on the geometry of the point employed, and that the radio interference accompanying the ionization was very definitely a function of the discharge characteristics. The maximum potentials required were of the order of 50 kv direct current, and it was essential that the voltage ripple be reduced to a minimum. The currents involved were of the order of microamperes and, since it was desired to record by means of the Duddell oscillograph both the discharge current and the accompanying radio interference, it was necessary that a current amplifier be employed. In recording the radio interference on this oscillograph, it was necessary only to provide an impedance-matching transformer between the low-frequency output of the radio set and the vibrator circuit.

The general test circuit used is given in figure 1. A full-wave, high-vacuum rectifier was employed for the high-voltage generator, and a loading capacitance of one microfarad was used to reduce the voltage ripple. The output voltage of the rectifier was determined by sphere gaps used within their proper polarity range and correlated with the voltmeter-coil instrument, designated as *V* on the diagram.

A two-stage linear vacuum-tube amplifier employing a type 57 and a *GE* type *FP* 110 tube was constructed. This is a resistance-coupled amplifier, and by means of a proper setting of the bias voltage E_0, it was possible to utilize the amplifier over its entire range for either positive or negative polarities on the point *P*. It was convenient, by connecting the deflector-plates of a cathode-ray oscillograph across R_1, R_2, or R_3, to obtain wave-form and amplitude checks against the indications of the Duddell oscillograph. These comparisons indicated that the latter oscillograph was responding with a satisfactory degree of accuracy. In the case of steep-front impulses of current or radio output, this oscillograph gave somewhat erroneous peak indications, and the vibrators displayed a minor tendency to fall into damped oscillations at their natural period. These characteristics, however, were not at all confusing.

The capacitance C_2 was necessary to prevent feedback oscillations in the amplifier circuit.

To examine the radio interference created by discharges from the point *P* to a plane, the conductor connecting this plane to the short-circuiting switch around A_1 and R_1 was carried once around the loop antenna of a Western Electric radio field-strength measuring set tuned for approximately 900 kilocycles.[4] The position of this coupling loop was so adjusted that no difference in radio output was observed when R_1 was introduced or short-circuited. The coupling was sufficiently loose to prevent the oscillations set up in the antenna circuit of the field strength set from feeding back into the current amplifier and giving erroneous indications in the amplifier output.

Types of Discharges

As the point discharge studies progressed, it was observed that when the point is positive with respect to the ground plane, there are three distinct types of discharges to be obtained. These discharge types are dependent on the geometry of the point employed and are illustrated in figure 2. Type 1 is characteristic of the discharge obtained throughout the range of voltages available, from a sharp, slender point. In total darkness, a small bead of ionization is visible at the end of the point and a tapering sheath of ionization extends for a short distance back from the point. An extremely interesting characteristic of this type of discharge is that no normal-frequency radio interference accompanies it.

The discharge indicated as type 2 is characteristic of that obtained from points

Figure 2. D-c corona discharges

Electrodes: point to plane
Polarity: positive
Spacing: 10.2 centimeters
Voltage: 44.0 kv

Type 1—Point: sharp, slender; current: 42.5 microamperes

Type 2—Point: number 0 steel needle; current: 48.0 microamperes

Type 3—Point: 60-degree conical; current: 41.5 microamperes

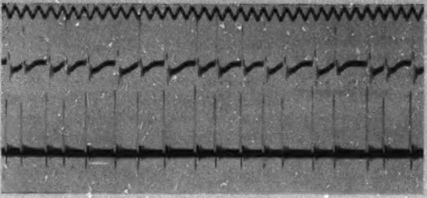

Figure 3. D-c corona discharge characteristics

Electrodes: 60-degree point to plane; spacing 10.2 centimeters

Point positive, plane grounded

$E = 15.2$ kv, $I = 2.0$ microamperes; upper, radio noise; lower, current with zero line; timing wave: one kilocycle

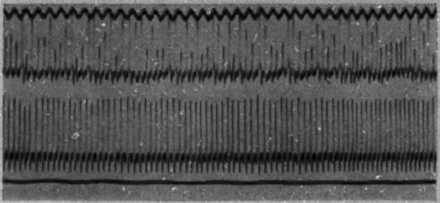

Figure 4. D-c corona discharge characteristics

Electrodes: 60-degree point to plane; spacing 10.2 centimeters

Point positive, plane grounded

$E = 38.0$ kv, $I = 28.3$ microamperes; upper, radio noise; lower, current with zero line; timing wave: one kilocycle

which have a rather acute angle of backing. That is, in general, if the angle made by the surface of the point with its center line is of the order of 30 degrees, and the point is carefully polished, this type of discharge will almost always occur. It may be described as a long, sharp ionized needle extending a considerable distance out from the point, and the current accompanying it for a given voltage is characteristically high. The radio interference produced by this type of discharge is severe and is characteristically harsh.

The type of discharge practically always obtained from a rough point or one which has a rather blunt backing, such as a conical point with sides making an angle of 60 degrees with the center line, is that illustrated as type 3 in figure 2. In this case, there is a typical bead of ionization adjacent to the point proper, and then a rather slender stem extending below the bead for a short distance before the discharge blossoms into a broad plume. The current drawn by this type of discharge is in general the lowest of the three and the radio interference produced has a characteristic musical note. The pitch of this note may run from the order of several thousand cycles per second down to less than 100 cycles per second, and is exactly similar to that described as being observed under certain conditions in airplane flight tests. It would appear, then, that at least type 2 and type 3 discharges occur from airplanes in flight under certain storm conditions.

OSCILLOGRAMS

Oscillographic records of point-discharge currents and the accompanying radio disturbances bring out a number of interesting and fundamental characteristics. The oscillogram of figure 3 shows the discharge current and radio noise characteristics of a 60-degree positive point, spaced 10.2 centimeters from the ground plane and operating at a potential of 15.2 kv. The average current, as indicated by a D'Arsonval instrument, was 2.0 microamperes. The scales were such that the current zero line blends with the actual current wave between the impulse peaks. The timing wave employed was 1,000 cycles per second, and the average frequency of the current impulses was approximately 500 cycles per second.

It is important to note that the radio noise surges occur exactly in synchronism with the current impulses, there being no radio output during the intervals of steady current flow. These current impulses, when viewed on the screen of a cathode-ray oscillograph employing a high-speed sweep, are very similar to those of an impulse generator. Figure 13 contains typical cathode-ray oscillograms of both the positive and the negative discharges. The individual steep-front impulses superimposed upon a steady direct current are shown in detail. It is evident that these impulses create the interference response in the radio receiving equipment. This subject will be treated further in the section, "Nature of Radio Interference Arising From Corona Discharges". The actual positive discharges used for the above oscillograms were of type 3.

When the voltage on the same point was increased to 38 kv, the current increased to 28.3 microamperes, and the radio noise and current appeared as is shown in the oscillogram of figure 4. The individual impulse character is still present in the current wave, but the impulses are spaced much more closely, the frequency now being of the order of 2,200 cycles per second. The radio interference, although somewhat irregular in character has the same general frequency

Figure 5. D-c corona discharge characteristics

Electrodes: 45-degree point to plane; spacing 10.2 centimeters

Point positive, plane grounded

E ‖ 43.5 kv, $I = 42$–47 microamperes; upper, radio noise; lower, current with zero line; timing wave: one kilocycle

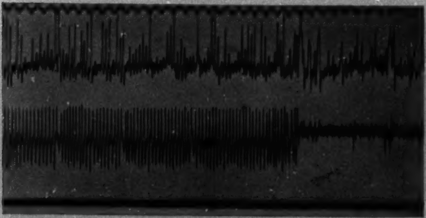

Figure 6. D-c corona discharge characteristics

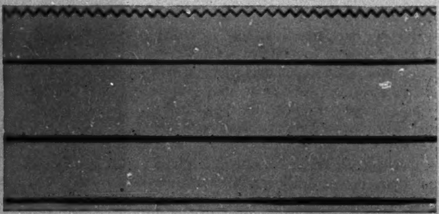
Electrodes: slender, sharp point to plane; spacing 10.2 centimeters; point positive, plane grounded; $E = 43.2$ kv, $I = 40.0$ microamperes; upper, radio noise; lower, current with zero line; timing wave: one kilocycle



Type $1'$—Polarity, negative; current, 49.6 microamperes

Type 3—Polarity, positive; current, 41.5 microamperes

Figure 7. D-c corona discharges

Electrodes: 60-degree point to plane
Spacing: 10.2 centimeters
Voltage: 44.0 kv

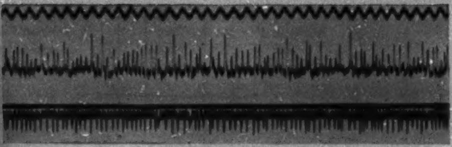


Figure 8. D-c corona discharge characteristics

Electrodes: 60-degree point to plane; spacing 10.2 centimeters

Point negative, plane grounded

$E=16.6$ kv, $I=3.0$ microamperes; upper, radio noise; lower, current with zero line; timing wave: one kilocycle

as the impulses in the discharge current. The slightly wavy zero line was due to a parasitic voltage picked up by the highly sensitive amplifier employed in the work.

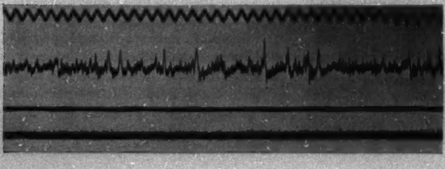
When the electrode was changed from a 60-degree to a 45-degree point, the discharges obtained were somewhat unstable in that they would occasionally shift back and forth from type 2 to type 3. The 45-degree point is on the border line between the geometry which consistently gives the type 3 discharge and that which gives type 2. The oscillogram of figure 5 was taken with this point operating at 43.5 kv to the ground plane. At the moment the exposure was made, an observer reported that the discharge changed from type 3 to type 2, and the record of this change is given on the oscillogram. The typical high-frequency succession of current impulses produced by the type 3 discharge is indicated in the first part of the oscillogram. On three occasions, however, there were breaks indicating that a change in discharge type was about to occur. Near the end of the oscillogram this change did occur, and the irregular current wave and associated radio interference typical of the type 2 discharge are shown in the last one-third of the record. It is indicated that there was a distinct change in the character of the radio interference in that the definite periodicity of the output impulses was largely gone. It is also of interest that the current increased from 42 microamperes during the type 3 discharge to 47 microamperes during the type 2 discharge.

Figure 9. D-c corona discharge characteristics

Electrodes: 60-degree point to plane; spacing 10.2 centimeters

Point negative, plane grounded

$E=36.2$ kv, $I=28.3$ microamperes; upper, radio noise; lower, current with zero line; timing wave: one kilocycle



It has been stated that the type 1 discharge which is obtained from sharp, slender positive points is free from radio interference. This characteristic is illustrated by the oscillogram of figure 6. The radio output is shown to have contained no interference whatever, while the current wave shows a number of very small impulses. These disturbances were evidently not sufficiently great to create any interference in the radio receiving set when tuned for normal frequencies.

After the earliest types of points had been subjected to a rather complete study under positive polarity conditions, the high-voltage generator was reversed and the studies were repeated for negative polarities. It was soon learned that all types of points, when of negative polarity, give discharges having essentially the same appearance. They seem similar to the type obtained for a positive sharp, slender point. A comparison between the type $1'$ discharge obtained on negative polarity and the type 3 obtained when positive, for the same identical point, is given in figure 7. It will be noted that the glow at the point of the electrode is very intense and restricted in the negative case, and that the current is approximately 20 per cent higher than for the same voltage when positive. Microscopically, the type $1'$ discharge negative is different from the type 1 positive when the negative discharge is obtained on anything but the sharp, slender point. On the bluntly backed point, the negative discharge appears to be a very small but intense, localized plume of ionization in contrast to the very much larger but less intense type 3 discharge obtained when the same type of point is of positive polarity. As brought out later, there is a very fundamental difference between the negative discharges from sharp, slender points and those from the bluntly-backed type of points.

The radio interference produced by the negative discharges was erratic in its character for all types of points except the sharp, slender one illustrated in figure 2. In this case, again, no perceptible interference was produced within the range of voltages available for the test.

The oscillogram of figure 8 compares with that of figure 3 with the difference that the former is negative and the latter is positive. The currents and voltages were of the same order of magnitude and identical points were used for both. It is shown that the negative discharge current, in common with the positive as illustrated in figure 3, is made up of a con-

tinuous value with a superimposed high-frequency series of small impulses. The frequency of these impulses is of the order of 2,000 cycles per second as compared with approximately 500 cycles per second in the positive case. The amplitude of the negative impulses is considerably less than that of the positive. Again, the radio interference is well synchronized with the current impulses although somewhat less regularly so than in the positive case.

For the very low discharge currents, it was observed occasionally that in the negative case also an irregular musical note was produced by the interference in the radio receiver. When the voltage is increased to higher values, the negative impulses lose their individual distinction. In the case of most types of points, the interference becomes very erratic sometimes rising to high values and then dropping off to practically nothing only to rise again, perhaps to intermediate values, as the voltage is slowly changed.

The oscillogram of figure 9 compares with that of figure 4 in that the points and discharge currents were identical with polarities reversed. In the positive case, the radio interference peaks were much higher than in the negative case although the latter condition seemed to give the more irregular interference. Close observation will bring out the fact that the current wave in the negative case is made up of a continuous value plus a heterogeneous succession of current impulses. A great many of these impulses will be observed to start in the positive direction. In other words, the average current is negative, but many of the impulses are in such a direction as momentarily to reduce the current rather than increase it as is practically always the case with positive polarity. This reversal phenomenon was particularly evident for the larger values of discharge current when the oscillograph screens were observed visually. The cathode-ray oscillogram of figure 13*C* indicates the erratic character of the negative discharges for currents well above the threshold value.

In the experimental work with negative discharges, the 60-degree point was practically the only one that could be depended on to give finite radio-interference characteristics of any regularity whatever. Furthermore, points that were made of steel or copper were rapidly altered in their characteristics by oxidation and positive-ion bombardment. Points constructed of tungsten gave much better results for operation over long periods of time.

An oscillogram of the sharp, slender point operating at 39 microamperes negative is shown in figure 10. This oscillogram compares with that shown in figure 6, the difference being only in polarity. Again, there is no perceptible radio interference and the current contains no apparent ripple. It should be explained that the slight appearance of radio interference was due to an extraneous disturbing factor, foreign to the test setup.

Characteristic Curves

A series of discharge-current and radio-interference data was taken on each of several different types of electrodes. Typical curves obtained from these data are given in figures 11 and 12. The discharge characteristics of a 30-degree conical point to plane are shown in figure 11.

It is indicated that the negative currents were considerably higher throughout the entire range than the positive, and that the negative radio interference was very erratic. The character of discharge occurring during this test was type 1′ for the negative, and throughout most of the range, a combination of types 2 and 3 for the positive.

The very interesting and useful discharge characteristics of the sharp, slender point are given in figure 12. It is shown that the currents for this electrode were the highest of all the different points tested, but the radio interference, with the exception of one very weak disturbance at a relatively low voltage, was zero throughout the entire range. During practically all of the tests with this particular point, no interference was obtained on either polarity over the entire voltage range. The data indicating a small amount of interference were included on this particular curve because on one occasion a minor disturbance did occur in that region.

No attempt was made to formulate a mathematical law of the discharge current as functions of voltage, spacing, and point configuration. Such a study is sufficiently involved to warrant special consideration. For both polarities and for all of the different types of points, it is indicated, however, that the discharge currents in the region near the threshold voltages are an approximate parabolic function of the voltage above the critical disruptive value. For the higher voltages, these currents approach a linear function of the point potential. It is indicated also that the sharpness of the point, as well as the type of discharge, has a definite bearing on the currents. As the points are made sharper, that is, as the included angle becomes less, the discharge current for both polarities becomes greater. For all of the conditions employed in these tests, the negative currents were observed consistently to be higher than the positive.

Mechanism of Discharge

The foregoing curves and oscillograms point clearly to the nature and mechanism of high-voltage, d-c discharges from points. Again, as in the case of a-c corona discharges from conductors, space-charge phenomena are controlling factors in the point discharge mechanism.[3,5,6]

When the discharge electrode is positive, and of a blunt-backed type such as the 60-degree conical point, a general ion migration seems to account for a continuous flow of current between the point and the ground plane. Positive streamers, composed of electron avalanches, periodically project into space from the point, creating positive space charges which momentarily reduce the gradients and block further ionization until they have become reduced in intensity to the point where succeeding streamers can develop. Since the entire point is somewhat symmetrical, creating a localized region of high electric field concentration surrounded by a relatively large background shield, the phenomena repeat with definite regularity. The frequency of repetition as well as the intensity of the streamers depends largely upon the voltage and, therefore, upon the current being discharged from the point. These individual positive streamers are responsible for the current impulses superimposed upon the otherwise relatively steady flow of current.

In the case of the sharper points with a less effective backing, the space charges do not build up with such definite regularity, and the positive streamers are of a more random character. The orderly repetition of current impulses, therefore, does not occur.

Surrounding the end of the extremely sharp point having a long slender shank, the positive space charge seems to build up to a stable equilibrium and remain there over a wide range of discharge currents. This space charge, with its internal gradient falling off rapidly from the point outward, blocks off the development of any positive streamers and, hence, no current impulses occur.

In the case of the negative polarity, the positive-ion space charges are established in the region of high potential gradients and tend to move in toward the point of discharge. As they approach it closely, the voltage gradients build up to the point where further impulsive discharges occur. This mechanism results in the extraction of large numbers of electrons from the electrode and its vicinity. For low values of negative discharge currents, these electrons move outward with relatively low velocities and create, momentarily, a neutral or even negative space surrounding the point. As more remote ions move in, the positive space charge is again established, and the process is repeated. These phenomena result in the negative current impulses appearing in the circuit between the plane and ground (see figure 13*C*). However, at the higher voltages, the clouds of electrons are projected with much higher velocities and result in the rapid creation of high positive space charges which actually block off, momentarily, the passage of more electrons out into the interelectrode space. Hence, the current appearing in the ground circuit tends to drop off abruptly as each of these high positive space charges is created, thus resulting in apparent positive impulses on the negative current flow. As these positive space charges move in toward the ionization point, breakdown occurs with great abruptness and, hence, the fronts of the current impulses are exceedingly steep although the impulses themselves are not large in magnitude. Professor Loeb and his associates have done considerable work on the physical nature of these ionization phenomena and have studied certain phases of the subject in great detail.[8]

Two of the most interesting characteristics brought out by the above tests are as follows:

1. A sharp, slender point can be caused to discharge positive or negative electricity, in amounts up to at least 40 or 50 microamperes per point, without creating any appreciable radio interference at frequencies up to several megacycles.
2. Rough points, which microscopically are sharp points with rather blunt backing, produce the most severe negative radio interference and also produce the musical-note type of positive interference.

Nature of Radio Interference Arising From Corona Discharges

The nature of d-c point discharges as brought out by the oscillographic study outlined in the previous section gave a very definite clue to the mechanism of the radio interference produced by such discharges. It was evident that the disturbances were created by the steep-wave-front current impulses. Particularly in the low-current positive discharge studies, it was obvious that each impulse was accompanied by a heavy shock in the radio.

The essentials of the circuit employed in these tests were such that the energy input to the radio receiver was through an inductive coupling between the circuit carrying point-discharge current and the parallel-resonance antenna circuit of the receiver. The impulsive currents, in flowing to ground through such an inductively coupled system, induce transient voltages in the antenna circuit of the radio receiver. These voltages drive the tuned antenna circuit into oscillation at its natural period, and since each resultant oscillation has a definite decrement due to circuit losses, the high-frequency disturbance carried into the radio-frequency amplifiers effectively is modulated and appears in the output circuit as a surge of energy. The intensity of this surge depends on the amplitude of the oscillation induced in the antenna circuit by the steep-wave-front current impulse. Since the induced voltage is equal to $M \cdot di/dt$, the steepness of wave front of the current impulse, as well as its magnitude, influences this voltage. A current impulse of high amplitude and steep wave front, therefore, would be expected to induce a severe oscillation in the tuned antenna circuit of the radio receiver and a resultant heavy surge in the output.

In many cases of radio disturbances produced by point discharges, the coupling of the discharge point, and of the space charge surrounding that point, to the radio antenna is capacitive. Here again the individual current impulses occurring in the discharge circuit produce similar, although much smaller, current impulses in the primary of the antenna-circuit coupling coil. The same mechanism, therefore, applies in this case as in the former with respect to the transient excitation of the tuned radio-frequency circuits.

IMPULSE EXCITATION OF OSCILLATORY CIRCUITS

It is evident that in every practical case, the coupling of the radio receiver to the discharge circuit is such as to cause steep-wave-front currents to pass through the primary of the antenna coupling transformer when similar currents appear in the corona discharge circuit. The subject resolves, therefore, into a study of the impulse excitation of oscillatory circuits. This problem has been studied analytically and is reported elsewhere.[7] A brief summary of the findings will be given here:

1. The steepness of front and amplitude of the impinging impulse have a direct influence on the magnitude of the oscillation induced in the tuned circuit.

2. The steepness of descent of the tail of the impulse, if it occurs at approximately one-half period of the resonant circuit, has a direct influence on the amplitude of the oscillation.

3. The area under the impulse-current wave for the first one-fourth period of the oscillatory circuit has a direct bearing on the magnitude of the induced oscillation.

4. Resistance in the discharge circuit, since it cuts down the amplitude of the current impulse and therefore the average rate of rise of the wave from zero to crest, reduces the amplitude of the induced oscillation. Figure 13 illustrates this property oscillographically. Since resistance does not greatly change the initial rate of rise of the front of the impulse, its effect is most pronounced for the lower oscillation frequencies.

5. Inductance in the discharge circuit, since it reduces the steepness of front of the current impulse, tends to cut down the amplitude of the induced oscillation.

The above summary indicates that not only resistance but also inductance in the high-voltage point-discharge circuits should be effective in reducing the impulse excitation of the tuned antenna circuit of the radio receiver. This analysis again indicates that the type of radio interference produced by these high-voltage discharges is of impulse excitation character, the only high-frequency oscillations appearing in general being those set up in the antenna circuit of the radio receiver, at the frequency for which it is tuned, by the impinging impulse.[*] It is evident, therefore, that any operation upon the interfering circuit which will eliminate or will lessen the amplitude and reduce the steepness of wave front of the individual current impulses will result in improved radio interference characteristics. Continuous, heavy ionization at the discharge point such as can be produced by the projection of an ionized liquid, by relatively low-voltage d-c arcs or by high-voltage, radio-frequency arcs, will result in the elimination of current impulses and their accompanying radio disturbances. The performance of such devices under high-velocity air movement conditions is uncertain.

From the above analysis, it is further evident that as the resonance frequency of the tuned input circuit of the radio receiver is increased to the high and ultrahigh-frequency regions, the amplitude of the induced oscillations created by the current impulses will decrease to a marked degree. For a given radio-receiver sensitivity, then, much less interference would be expected from the high-voltage point discharges in the high and ultrahigh-frequency regions than in the normal and low-frequency bands. Recent experience with ultrahigh-frequency equipment has borne out this prediction.

The influence of discharge resistors and inductors on the radio-interference characteristics of point discharges was examined experimentally, and typical results on a 50-degree conical point indicated that a series resistance of two megohms would produce a reduction of over 50 per cent. A further 50 per cent decrease in the remaining interference followed the introduction of a 37-milihenry inductor. This inductor was not of a particularly good radio-frequency type, but it did produce a definite improvement in the interference characteristics.

It follows then that the introduction of large amounts of resistance and inductance, with a minimum of distributed or shunt capacitance, in the high-voltage circuit as close as possible to the discharge point will result in minimized radio disturbances. Certain precautions, however, must be employed in using these resistors and inductors. The voltage of the point may be expected to change abruptly with each impulsive discharge when resistors and inductors are incorporated in the discharge circuit. To prevent these sudden changes of voltage from inducing current impulses in the radio antennas, some form of shielding about the point might be necessary.

Conclusion

It has been shown that there are at least three distinct types of positive corona discharges from pointed electrodes, and two less sharply defined types of negative discharges. All of these discharges, with the exception of one type which is common to both positive and negative polarities and occurs only on sharp, slender points, give rise to an impulse excitation type of interference in nearby normal-frequency radio-receiving equipment. The silent type of point offers excellent possibilities for the development of an airplane precipitation-static charge-dissipating device. Because of its fundamental mechanism, it seems probable that point-discharge interference will not exist in any appreciable magnitude in receiving equipment operating at the ultrahigh frequencies. Further studies are under way in the ultrahigh-frequency field and in the development of interference suppressors.

[*] In certain cases, parts of the circuit carrying the discharge currents are driven into complex, damped high-frequency oscillations and interfering energy is radiated directly. This mechanism, however, is believed to be the exception rather than the rule, particularly in direct-current corona phenomena.

Aircraft Precipitation-Static Radio Interference

E. C. STARR
MEMBER AIEE

Synopsis: Radio reception at normal frequencies on board high-speed, all-metal aircraft suffers severe interference under certain precipitation conditions. Flight research has shown that under these same conditions, an airplane will accumulate a relatively heavy electric charge. The resulting potential difference between this charged object and its immediate surroundings creates voltage gradients of sufficient magnitude on pointed and sharp-edged extremities of the craft to produce corona discharges. Local radio disturbances of varying character and severe intensity accompany these discharges.

Several different mechanisms were found to be involved in the production of the discharges, and currents of magnitudes greater than one milliampere were observed under severe conditions from a single point. Numerous graphic records were taken in flight showing the correlation between the charge and discharge currents at various points on the airplane. These records also illustrated the rapidly fluctuating magnitude of the discharges and indicated that their directions reversed rapidly under certain space-gradient conditions.

Ground tests involving the research airplane mounted on insulating supports and charged by means of a high-voltage rectifier, indicated that the radio interference and discharge currents observed in flight could be duplicated under controlled conditions on the ground. Further ground and laboratory tests verified and explained the recognized efficiency of the shielded radio loop in improving to a marked degree the signal-to-noise ratio in the presence of corona discharge interference.

The mechanism of the interference was studied intensively in the laboratory. Artificial airplane discharging devices involving trailing and projecting conductors terminating in special points and containing interference-suppressing resistors and inductors were developed. A simple but effective trailing discharge conductor to be projected and used in severe precipitation-static emergencies has been adopted by at least one large air transport company.

One of the elements essential to the success of modern scheduled aerial transportation is a reliable system of radio communication. Continuous contact with strategically located ground stations enables aircraft flight personnel to maintain accurate courses and to exchange important weather and dispatching information. As a further service, still in an experimental stage, the radio is making instrument or "blind" landing operations highly successful. The application of radio aids to aerial navigation is covered fully elsewhere.[1,2]

During normal weather conditions, these aids are successful in their operation, but at times when most needed, during heavy weather with low visibility, they may become erratic or entirely useless. Flight research has shown that certain precipitation conditions accompanying atmospheric storms cause large, high-speed, all-metal airplanes to become charged electrically and, subsequently, to discharge to the surrounding atmosphere producing local radio disturbances of severe intensity. It has been found that these charges are accumulated by a number of different mechanisms, and that the discharge is a process of maintaining the potential of the airplane at a value not greatly different from that of its surroundings.

Tests in flight and on the ground have indicated that these discharges are the same as those which can be created by high, direct voltages impressed upon point electrodes. An extensive study was made of the nature of these discharges and of means available for controlling them.

It is suggested that a systematic electrical discharging arrangement can be installed on airplanes to control effectively the accumulated charges and reduce the radio interference resulting from their dissipation to the atmosphere. In the form of a trailing wire, such discharging equipment has been installed on all of the transport airplanes of at least one of our major air lines. This trailing wire is so mounted that it can be projected into its normal position when severe static conditions develop and can be replaced economically when destroyed by contact with the ground during landing operations. Although this device is very simple and somewhat limited in its ability to discharge the airplane, it has, nevertheless, given a good account of itself in a number of different emergencies.

Radio Interference

In heavy weather, particularly in violent squalls and in air mass fronts, it is especially important that the airways radio ranges and marker beacons be operative. Under these conditions local cross winds of severe intensity may tend to drive the airplane far from its course unless the range signals can be received satisfactorily. Unfortunately, such weather conditions are usually accompanied by some form of precipitation. There may be snow, rain, dust, or frost crystals in the air. Experience has shown that an airplane, particularly of the all-metal variety, flying at speeds materially above 100 miles per hour into such precipitation, in general has all but its ultra-high-frequency radio reception very seriously impaired. The interference may appear in any one of, or in a combination of several different forms.

It has been known since the early days of radio communication that electrical discharges from conductors, either of low or high voltage, will produce local interference in receiving equipment. The making or breaking of a low-voltage circuit will produce a shock disturbance in the receiver. Low-voltage vibrating-type interrupters and machine commutators may produce such a rapid succession of these shock disturbances as to create a musical note in the receiver. High-voltage corona discharges on conductors and insulators are known to create serious radio interference.[3] On the airplane the high-voltage ignition system of the engine must be shielded very carefully to avoid the introduction of heavy shock interference into the receiving equipment.

Some of the radio interference created by an airplane flying at high speed into an area of precipitation is of such a type as to be susceptible to improvement by noise-suppressor circuits.[4] When the airplane is in a light snow of relatively large individual flakes, the interference created is generally of a typical low-frequency vibrator type. Such interference could be removed by noise-suppressor circuits. However, when the flight is through most forms of precipitation of normal density, the interference created is of such a continuous character that no noise-suppressor circuit at present avail-

Paper 40-117, recommended by the AIEE committee on communication, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted May 8, 1939; made available for preprinting May 20, 1940.

E. C. Starr is professor of electrical engineering at Oregon State College, Corvallis.

The valuable assistance of the communication department of the United Air Lines Transport Corporation in obtaining the flight data outlined in this paper is gratefully acknowledged. Assistance in the flight and ground tests was also given by Doctors A. A. Knowlton and Marcus O'Day of Reed College and by Professor R. H. George of Purdue University.

1. For all numbered references, see list at end of paper.

able has any beneficial effect. The interference ranges in nature from a harsh, rasping sound in the head phones to a varying, high-pitched musical note. The intensity frequently becomes so high as to make necessary the reduction of receiver gain to a point where the normal radio range signals in the absence of interference, could be read only a very short distance from the transmitter.

Such disturbing conditions may exist for only brief periods during the passage through a precipitation area or, in the event of flight along an air mass front, they may exist for a matter of 30 minutes or more. Under such conditions, the normal-frequency radio range cannot be read, and no reception of voice communication from the ground or other airplanes is possible. The flight personnel must, therefore, resort to dead reckoning to maintain the course at a time when the radio navigational aids are most essential.

Precipitation-Static Flight Research

As airplanes became larger and speeds became higher, the interference problem became more acute. A number of accidents were attributable directly to airplanes being off-course due to their having lost the radio range under storm conditions. Having then encountered unreported squalls for which no correction could be made, they were driven unknowingly into dangerous terrain. The hazard was recognized by pilots as well as by administrative personnel and efforts were started to attempt to solve the problem. At first it was thought that the interference was due to charged particles of precipitation impinging upon the exposed radio antennas. In an effort to eliminate this difficulty, the antenna conductors were covered with rubber insulation, but no improvement was obtained.

It was reported by a number of pilots that under certain cold, dry-snow and frost-crystal conditions, the airplane windshields had been seen to glow with a brush discharge. At times these brushes were reported to become so severe as to give the appearance of the windshield sparking over completely. Under these same conditions, the rubber deicers on the leading edges of the airplane wings were observed to glow with brush discharges, and at times to appear practically to spark completely across. The tips of the propellers were observed to glow at times with a typical Saint Elmo's fire.

These reports definitely established the existence of an electrical charging mechanism which was causing insulated areas on the airplane to attain very high potentials with respect to the ship itself. If that were the case, it was reasonable to assume that by the same mechanism the entire airplane was being charged to potentials considerably above that of the surrounding atmosphere. It was further evident, since the insulated surfaces such as windshields and rubber deicers were being charged to potentials considerably above those of the airplane proper, that the potential of the ship was being held down by some form of discharge mechanism. In other words, it appeared that the windshields and deicers were discharging to the ship, adding to the charge it was receiving by similar action, and the whole was discharging to the atmosphere. If such were the case, at least one source of the observed radio interference was the d-c brush or corona discharge from sharp extremities of the airplane to the atmosphere.

Figure 1. Interior view of precipitation-static research airplane showing synchronized graphic-recording milliammeters and current amplifiers

Recognizing this possibility, one of the large air transport organizations led a co-operative, systematic study of the problem. A regular ten-passenger, two-motor Boeing type 247-*D* transport airplane was withdrawn from passenger service and made available as a research ship. A number of the seats were removed and a test bench for scientific instruments was installed in their place. A partial view of the arrangement is shown in figure 1.

The exterior of the plane was equipped with a number of insulated charge- and discharge-measuring electrodes. Those which gave the most interesting results were as follows:

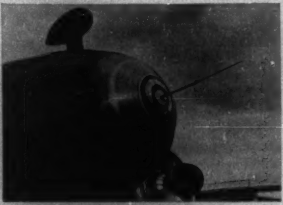

Figure 2. Nose electrode and nose plate installed on Boeing type 247-D airplane for precipitation-static research

1. A short rod projecting from the side of the fuselage directly behind the left propeller tips.
2. A sphere supported below the fuselage and behind the Pitot stub.
3. A 30-inch pointed rod projecting from the nose of the plane ahead into undisturbed air.
4. An insulated plate in the form of an annular disk, conforming to the streamlined shape of the nose of the plane.
5. Three pointed rods, each approximately 12 inches long, projecting from each wing tip.
6. A 30-inch pointed retractable rod extending rearward from the tail of the ship.

The nose electrode and nose plate are illustrated in figure 2. Each of the various electrodes was well insulated from the airplane and was connected through conductors to a terminal board beneath the test bench inside the cabin.

The instruments used in determining the currents of charge and discharge, and the polarity and character of these quantities were as follows:

1. Two highly-sensitive vacuum-tube electrometers.

2. A cathode-ray oscillograph.

3. Three synchronized graphic-recording milliammeters, driven by a three-element vacuum-tube ammeter.

4. A standard air-transport-beacon receiver.

5. A special Bell Telephone Laboratories receiver equipped with noise-suppressing circuit.

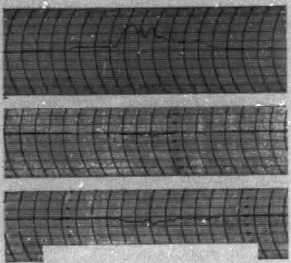

Figure 3. Airplane discharge currents; nose plate, nose and tail electrodes

Upper—Nose plate; center—nose electrode; lower—tail

Precipitation: dry snow

Scales: upper 0.1, others 10 microamperes per major division; eight units per minute; plane negative for negative deflections; Boeing 247-*D*

6. Various microammeters and auxiliary equipment.

The graphic recording instruments from which the most orderly data were obtained, together with their driving vacuum-tube ammeter, are shown in figure 1.

The airplane was also equipped with an intercommunication telephone system which could be connected to the output of a radio receiving set being driven by any one of the following antennas:

1. The standard "belly V" beacon receiver antenna.
2. The short-wave transmitting antenna.
3. A shielded loop projecting beneath the fuselage of the plane and located approximately on a line between the two engines.
4. A shielded loop in a streamlined housing above the nose of the airplane.
5. A diagonal antenna extending from one end of the horizontal fin to a position approximately midway of the fuselage of the ship.
6. An interchangeable shielded loop or crossed dipole projecting forward from the nose of the ship.

Neither of the last-named antennas could be employed at the time the nose electrode and nose plate were in use. For a time a straight-wire antenna enclosed in a nonconducting tube coated with a high-resistance conducting compound was installed beneath and parallel to the fuselage of the airplane.

In the early work an attempt was made to observe the charge and discharge currents on indicating instruments and to correlate these currents with the radio interference observed on the different antennas. It was soon learned, however, that the conditions change so very rapidly that it was not possible to take notes fast enough to obtain an accurate record.

Before many tests had been made, it was observed that all of the wire antennas gave approximately similar results. The one exception was the antenna extending toward the rear of the ship and this one was found to have a consistently higher noise pickup property than the others. It was also observed that the shielded loop antennas, in agreement with previous tests, gave a noticeably higher signal-to-noise pickup ratio than any of the wire antennas.

Since the standard "belly V" beacon receiver antenna gave results essentially as good as any of the wire antennas, it was used as the comparison standard throughout most of the tests. It was found that the interference picked up by this antenna became severe as soon as any of the pointed electrodes began to pass an appreciable current. When the electrode currents exceeded the order of 5 to 15 microamperes, the interference in the "belly V" became so intense as to make impossible the reception of radio-range signals even when relatively near the range transmitter.

The discharge interference picked up by the shielded loop antennas was noticeably much less than that picked up by the "belly V", but when the electrode currents approached orders of magnitude of 50 microamperes or more, the loop interference became excessive.

CHARGE AND DISCHARGE RECORDS

In order to determine something of the mechanism of the airplane charge and discharge phenomena, the graphic recording milliammeters were so connected as to obtain simultaneous records of three currents. For some of the tests, the nose plate, nose and tail electrodes were used, and for other tests the wing tip and tail electrodes were employed.

A great number of records were obtained by flights in different types of precipitation in various cloud formations, and examples of these records are given in figures 3, 4, 5, and 6. The record of figure 3 is low in intensity but is typical of those obtained under dry snow conditions. It is indicated that the nose plate charged negatively, whereas the nose and tail pointed electrodes discharged positively. That is, in the case of the nose-plate record the airplane was positive with respect to the plate, while in the case of the nose and tail electrodes, the ship was negative with respect to the points. Since no appreciable ionization could be taking place from the nose plate, it was obvious that this surface was charged negatively by the precipitation in which the airplane was flying. The points, however, since they would readily admit of ionization, were discharging this negative electricity into the atmosphere. This was a typical mechanism frequently observed in relatively stable dry-snow and frost-crystal areas.

A typical case of the airplane discharging heavily from all electrodes on which measurements were being taken is recorded in figure 4. The very consistent character of the negative electricity discharge from both wing tips and from tail electrode is shown. It will be noted that the change of intensity of the dis-

Precipitation: wet snow

Scales: ten microamperes per major division, eight units per minute; plane negative for negative deflections; Boeing 247-*D* charge from any one electrode was accompanied by a similar change in the discharges from the other two electrodes. It is obvious that the ship was being charged negatively very strongly by some action of the precipitation in which it was flying. In this case the precipitation was heavy snow. The uniform vertical deflections present at periodic intervals in each graph were created by a special timing device and represent one-minute intervals. The radio interference accompanying the discharge in this case was very severe and of harsh character.

Many of the records indicated high longitudinal or transverse voltage gradients across the airplane. The ionization electrodes on the extremities of the ship under these conditions indicated currents flowing from nose to tail or from wing to wing. Such conditions were usually transitory, and sudden reversals of gradient frequently occurred.

An interesting condition of high transverse gradients is illustrated by the record in figure 5. In this case, the right wing was in an area which was very strongly negative with respect to that surrounding the end of the left wing. Transverse currents of considerable magnitude were flowing from wing tip to wing tip as a result of this short-circuiting action. Near the end of the record a slight reversal of the gradient occurred. It is interesting also that in this case the tail electrode was relatively inactive. Its tendency was to alternate somewhat between negative and positive discharges of relatively weak magnitude.

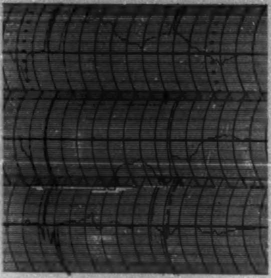

Figure 5. Airplane discharge currents; wing-tip and tail electrodes

Upper—Right wing; center—left wing; lower—tail

Precipitation: light, dry snow

Scales: Ten microamperes per major división, eight units per minute; plane negative for negative deflections; Boeing 247-*D*

A condition different from any other so far discussed is brought out in the record of figure 6. In this case the nose plate was receiving positive electricity at a time when both the nose and tail electrodes were discharging negatively. A period of longitudinal gradient reversals affecting only the ionization points also is brought out in this record. The most interesting feature, however, is that the ionization electrodes were indicating heavy negative discharges at a time when exposed surfaces, represented by the nose plate, were receiving positive electricity. This condition indicated charging mechanisms that were apparently considerably different from those in the other records. The precipitation into which the airplane was flying was evidently either neutral or positively charged, or the impact of the air foils with this precipitation resulted in a positive charge. The ship, however, was being charged negatively as indicated by the negative discharges. This leads to the belief that the propeller action in breaking up the heavy snowflakes was such as to create a resultant negative charge on the airplane even though some positive charge was being accumulated by contact of the air foils with the charged snow flakes.

A careful study of the discharge records leads to several rather definite and other somewhat obscure conclusions. It is well known that cloud masses can become heavily charged by some type of thermal activity similar to that described by Simpson.[8] When an airplane flies into one of these charged areas, it must gradually attain the potential of that area, first by electric induction and later by actual contact with the charged precipitation. A potential gained in such a manner would place the ship at the same potential as the region in which it is flying, and hence would result in no localized voltage gradients that would produce corona discharges.

It is evident then that the contact with and breaking up of particles of precipitation by the air foils and propellers results in charging the plane to a potential different from that of the particles themselves. The extreme windshield and deicer potentials observed at times indicate that contact with and breaking up of dry-snow and frost-crystal particles results in extremely high charge accumulations. The record of figure 6 indicates that the action of the air foils of the propellers may be such as to produce negative charges on the airplane from positively charged or neutral precipitation.

In large storm areas, where the precipitation is rather general and where the vertical air currents are not pronounced, a reasonably uniform charging condition may exist. At such times the airplane will attain a high negative potential with respect to the surrounding atmosphere and will discharge continuously. However, in squally conditions, notably in heat clouds, the charged areas are not at all uniform. The airplane may, therefore, fly from an area of low charge to one of much higher potential in a very brief period of time and, in so doing, the ship must be brought to the potential of the new region. This change will result in heavy corona discharges of short duration between the plane and the higher-potential region into which it is flying. Subsequently, as the ship leaves this high-potential region and enters one of lower potential, the reverse operation will take place, that is, the ship will discharge its higher voltage to the lower potential region. Most of the high longitudinal gradients illustrated in the records were due to conditions of this character. The so-called "crying" or musical-note static in the radio receivers was observed to accompany these particular conditions, and it will be shown in a companion paper "High-Voltage D-C Point Discharges" that positive corona dis-

Figure 6. Airplane discharge currents; nose plate, nose and tail electrodes

charges under many conditions characteristically produce this type of interference. Under certain rather critical conditions, the negative discharges will also produce the musical note interference.

It was found that the discharge currents under practically all flight conditions fluctuate very rapidly. Some of the observations indicated transverse currents as great as one milliampere, and discharges from the tail electrode approaching the same order of magnitude were recorded on a few rather extreme occasions.

The characteristic Saint Elmo's fire discharge, so frequently reported as being observed during the hours of darkness at the propeller tips, is undoubtedly due to two elements. The first is that these propeller tips are very sharp, and since they extend out a considerable distance from the shielding influence of the fuselage and wings, they constitute excellent discharge points. The second is that due to the very high peripheral speeds of these propellers, as well as their pitch, a low-pressure region exists near the tips. Since ionization occurs much more readily at low absolute pressures than in the normal atmosphere, the discharges would take place in these regions at reduced potentials.

The influence of size and speed of aircraft upon the charging action observed in precipitation areas and hence the influence of these same factors on the radio interference created is pronounced. The larger and faster craft, since their frontal areas are larger and since their speeds are greater, make contact with more particles of precipitation per unit time than the smaller ships. The result is a definitely higher charge and discharge rate together with a greater volume of interference. The broad wing spans and great axial lengths of the larger ships cause them to span greater areas and hence to create greater disturbances in the regions of high voltage gradients.

Jets of water directed into the rapidly revolving propellers with the airplane at rest caused charges to accumulate on electrodes located in the slip stream. These charges were either positive or negative depending on the salt content of the water. It appears, therefore, that this charging action is similar to that obtaining when falling drops of water are subjected to a rising jet of air.[6,7]

Since various areas on airplanes experience such pronounced charging actions under certain storm conditions, it is evident that very thorough bonding should be practiced between all conducting parts of the airplane.

Any exposed insulating surfaces such as the windshields, the deicers, insulating housings over radio loops and the exposed landing wheel tires, will, under certain conditions as outlined previously, accumulate electric charges which will dissipate themselves in the form of sparks to nearby metal supports. This condition can be alleviated only by causing the surfaces of the offending elements to provide a leakage path to nearby bonded metal parts. It is interesting to observe that the ice caps, which under certain precipitation conditions will form on the leading edges of the air foils, can have charges developed on their exposed surfaces. Since the ice accumulated at high altitude forms a very excellent insulator, the ice cap creates, in effect, a localized insulated area similar to the windshields and plain rubber deicer boots.

High-Voltage D-C Ground Tests

The rapidly fluctuating character of the voltages encountered in the flight tests indicated the desirability of making tests on the airplane with more accurately controlled voltages. It was felt that flight conditions might be simulated by mounting the plane on insulators and charging it to a sufficiently high direct potential to cause exposed points to go into corona. Information had been obtained on the magnitudes of discharge currents to be expected under storm conditions and the type of radio interference created had been observed carefully. It was felt that if these same conditions could be developed on the ground under accurately controlled voltages, much more consistent results could be obtained.

In line with these thoughts, the research airplane was placed in a large hangar and mounted on high-voltage insulating supports. Adequate insulation and clearances were provided to prevent the appearance of brush discharges from the landing gear and wheels toward the concrete floor, or from the extremities of wings, tail surfaces, and propellers. An improvised high-voltage rectifier, utilizing X-ray equipment, was assembled and adjusted to give a maximum potential of approximately 100,000 volts to ground.

With a potential of the order of 50,000 volts applied to the airplane, conducting surfaces connected to ground were brought into close proximity to the various discharge points mounted on the airplane. Observers inside the cabin noted that currents of the same order of magnitude could be drawn from these points by this arrangement as were obtained in flight. They furthermore observed that the radio interference created by such discharges was of exactly the same character as that which had been obtained during the flight tests.

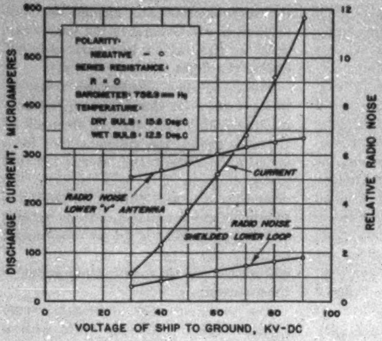
Following these preliminary tests, arrangements were made to suspend conducting points from the tail electrode of the ship toward the concrete floor for a series of discharge tests. It was felt that if the concrete floor were used as the ground plane, the currents would distribute so widely and return to the generator through such a broad conducting medium as to prevent the creation of disturbances in the radio antennas due to these currents.

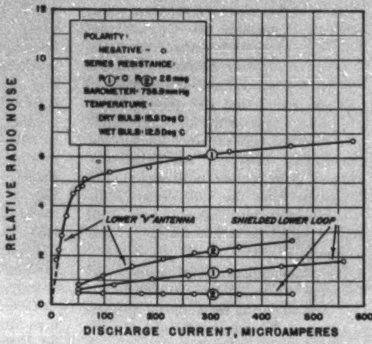
For the first series of tests, a 0.25-inch steel rod was sharpened with a rather long taper and was suspended 11 inches from the concrete floor. High-voltage ignition conductor was used for the support in order to eliminate the possibility of corona discharges from the conductor itself. The tail electrode was well covered with rubber insulating tape to prevent it from going into corona. Observations made during the hours of darkness indicated that no visible discharges were taking place from any part of the plane other than the point where the discharge was desired.

A local signal generator, modulated at a frequency of approximately 1,000 cycles per second, was employed to create a background carrier wave for which the beacon receiver was tuned. It was so located, together with the gain setting of the radio receiver, as to produce a rectified output in the headphone circuit of 0.5 microampere. For all tests, the receiver gain setting was kept at approximately the same point, and a signal of 0.5 microampere was obtained by so locating the local signal generator as to produce the desired output.

The results of the rod-point tests were somewhat erratic, but they checked the flight-test data very satisfactorily. It had been observed in storm flying that the shielded loop had much better signal-to-noise pickup characteristics than the open antennas, and here again exactly the same characteristics were exhibited.

It was felt that the rather large backing of the rod point was producing a shielding action that was influencing its characteristics at the higher voltages. Accordingly, a 7.5-inch length of tungsten wire with a diameter of 0.007 inch was suspended from the same support with the spacing reduced to three inches. The polarity of the ship remained negative, and the same local signal generator output was maintained as used previously. The results of the tests on this electrode





Figures 7 (left) and 8 (right). Airplane discharge characteristics

Discharge electrode: vertical wire 7.5 inches long, 0.007 inch diameter, 3 inches from concrete floor

Background noise: local signal generator, 0.5

are shown in figures 7 and 8. The maximum currents were of the order of 580 microamperes, and the radio interference as obtained from the lower or "belly V" antenna was severe throughout the entire voltage range. The shielded loop in this case also gave considerable interference for the higher current values, tapering down to relatively low interference at the lower voltages. Again, it was observed that the shielded loop provided a very favorable signal-to-noise ratio over the open antennas.

A resistance of 28 megohms was then connected in series with the discharge point and further tests were made. The data obtained with this arrangement are given in figure 8. It is shown that the insertion of resistance reduced the interference for a given discharge current to a marked degree. The interference pickup of the shielded loop was actually reduced to zero throughout the entire range of currents observed. Although some interference was still obtained from the open antenna, its performance was greatly improved.

These results immediately suggested the possibility of using in flight some type of trailing discharge conductor. The flight tests had indicated that the interference problem could be solved only by preventing the charging of the airplane to potentials greatly different from those of the surrounding atmosphere, or by dissipating these charges without disturbing the radio receiver. It was obvious that if the potential of the aircraft, by means of some discharging device, could be maintained at a value near that of the surrounding atmosphere, then no corona discharges could take place except in the event of passing through high-gradient regions where the airplane is effectively short-circuiting high differences of potential. Since these latter conditions are only transient in their character, they are not particularly objectionable. This trailing-wire discharger, with high-resistance noise suppressors, has been tried in flight and found to be very beneficial under most conditions.

At least one large air transport corporation has installed such trailing wire devices on all of its transport airplanes and has found them to be of material assistance in combating the precipitation-static problem. In this case, the trailing wires are contained in small cartridges and can be released from the tail of the airplane when severe static conditions arise. Normally, they are totally enclosed and, hence, are not subject to mechanical fatiguing and failure when not in use.

After a satisfactory amount of negative-polarity data had been obtained, the rectifier was reversed and provisions were made for obtaining positive-discharge data. Because of the very much greater sparking distance of point-to-plane electrodes with point positive than with point negative, it was necessary to increase the spacing between the end of the fine tungsten wire and the concrete floor from 3 inches to 7.5 inches. Otherwise, the setup employed was exactly the same as for the negative tests. The data obtained from these tests indicated some rather peculiar characteristics. Reference to the curves of figure 9 will show that as the current was raised slowly from zero to 110 microamperes, the interference received by all antennas was practically zero. Then, very suddenly the interference jumped to a high value, and as the current was further increased, continued on to still higher values. Observations of the discharge point indicated that prior to the sudden burst of interference the discharge was in the form of a very fine point of localized ionization. At the instant the interference started, a long ionized streamer was observed to burst out from the end of the discharge electrode. When the voltage was slowly reduced, the interference remained fairly high on down to low values of discharge current. These characteristics brought out the fact that the presence of ionization streamers was responsible to a considerable extent for the radio interference produced by the positive corona discharges. This phase of the subject is treated in detail in the companion paper, "High-Voltage D-C Point Discharges".

Again, the insertion of a discharge resistance of 28 megohms resulted in a marked improvement in the radio noise characteristics. Curve 2 (solid) of figure 9 illustrates the improvement obtained by the use of resistance. This curve is for decaying currents and represents ionized-streamer discharges from the highest to the lowest values. Curve 2 (dotted) indicates that the resistance completely eliminated the noise pickup of the shielded loop.

Co-ordinated Laboratory and Analytical Studies

The data obtained from the ground tests on the research airplane emphasized the necessity for additional basic studies in three different fields. The work to be covered was as follows:

1. The character of high-voltage d-c point discharges.
2. The mechanism of radio interference as produced by corona discharges from point electrodes and the possibility of suppressing this interference.
3. The fundamental characteristics of receiving antenna, particularly the shielded loop.

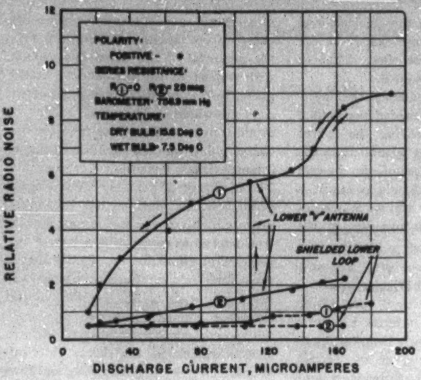


Figure 9. Airplane discharge characteristics

Discharge electrode: vertical wire 7.5 inches long, 0.007 inch diameter, 7.5 inches from concrete floor

Background noise: local signal generator, 0.5

The first of these subjects was studied in considerable detail and is reported in the companion paper referred to above. Figures 10, *a* and *b*, illustrate typical results of this work. For the type of point and the current employed in this case, the discharges of both polarities created the typical musical-note interference. The audio frequencies were much higher for the negative than for the positive discharge. It is shown that in both cases the discharge current is composed of a small ion, migration component plus a series of superimposed impulses of extremely steep wave front.

The bursts of radio interference are shown to coincide exactly with the fronts of these superimposed impulsive discharges. The radio disturbance is evidently the result of the tuned input circuit of the receiver being set into oscillation at its resonant frequency by the extremely steep-wave-front impulses. It is, therefore, a special case of the impulse excitation of oscillatory circuits. The interference mechanism falls in the classification of the second subject enumerated above and is treated in detail in the paper on point discharges.

Of particular interest was the finding that pointed electrodes with rather blunt backing and those of approximately hemispherical section, in general gave severe radio interference of widely varying character for both polarities of discharge. It was found, however, that sharp, slender points, that is, points having a terminal diameter of the order of 0.003 inch and having a very small included angle, produced a type of discharge on both polarities, and for all values of currents up to at least 50 microamperes, that was totally free from any radio interference in receivers operating up to several megacycles. This characteristic offers an extremely useful possibility for the development of improved airplane discharging systems. This matter will be treated in detail in a later section.

The third subject has a direct bearing on the aircraft problem and will be discussed in the following section.

Radio Receiving Antennas

Energy abstracting devices for radio-receiving equipment fall into three general classes:

1. The extended-conductor or open-wire antenna.
2. The simple loop antenna.
3. The shielded loop antenna.

The extended-wire type responds to the traveling electromagnetic wave and is also sensitive to any electric field in its vicinity. The true wave of electromagnetic radiation is composed of equal electric and magnetic components, and the voltage induced in the open antenna is essentially the same as that created in space by the passage of the wave. Induction fields, however, preponderantly electric or magnetic, can be caused to exist but their space coverage is relatively very limited. An extended-wire antenna in the presence of these induction fields will respond to both types (appendix III of reference 5).

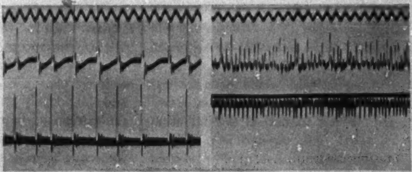
The unshielded loop antenna may be of either a balanced or unbalanced type. In the latter case, the loop will respond to both magnetic and electric fields. The magnetic response is essentially by transformer action. The electric response is due principally to charging currents flowing through the loop circuit to ground.

The balanced loop responds well to magnetic excitation, again by transformer action, but is very insensitive to electric excitation. In this case, the charging currents due to electric fields flow to ground equally in both directions through the loop, thus effectively cancelling any pickup which might result. If the midpoint of this balanced loop is grounded, a similar cancelling of electric-field pickup will occur.

The shielded radio loop, when shielding is composed of a discontinuous metallic tube surrounding the turns of the loop and is balanced to ground, is responsive only to the magnetic field. In this case, any changing electric field terminating on the loop produces currents which are conducted to ground in practically equal magnitudes and in opposite directions around the two parts of the shield. Consequently, no potential is induced in the loop proper due to these charging currents flowing to ground. Any improvement in the shielding design which will tend to maintain a balance between the charging currents flowing to ground through the two sides of the shield, will be beneficial in its results.

The Shielded Loop Antenna

It was brought out very definitely in the sections on flight research and ground tests that the shielded loop possessed marked advantages over the extended-wire antenna in its ability to discriminate between the desirable signal and undesirable "static" interference. This feature has been known for several years, particularly as regards effectiveness with certain types of static, and it has been employed



A—Point positive; $E = 15.2$ kv, $I = 2.0$ microamperes *B*—Point negative; $E = 16.6$ kv, $I = 3.0$ microamperes

Figure 10. D-c corona discharge characteristics

Electrodes: 60-degree point to plane; spacing 10.2 centimeters

Upper, radio noise; lower, current with zero line; timing wave: one kilocycle advantageously in a number of fields. Its effectiveness in the attenuation of precipitation static on aircraft is due to the fact that this static interference originates fundamentally as a high-voltage low-current discharge phenomenon. The electric fields associated with these discharges are necessarily intense while the magnetic fields, due to the relatively feeble character of the currents, are very weak.

It has been shown that the discharge currents are composed of steady values with superimposed double-exponential impulses. Such currents can be represented by a series of multiple-frequency waves. These waves will produce true electromagnetic radiations. However, since the a-c components are very small, the radiation fields, which are functions of the currents, necessarily will be weak. The electric induction fields, on the other hand, are relatively intense because the voltages involved are of the order of several thousand, and the distances from the source of the interference to the antennas are not great. As a matter of fact, for the normal radio frequencies, these distances are only of the order of a small fraction of a wave length. An open antenna should, therefore, respond strongly to the electric fields in the vicinity of the corona discharges, and weakly to the magnetic fields accompanying these discharges (appendix III of reference 5).

The properly shielded loop, however, as has been shown in the previous section, rejects the electric induction interference and accepts only the magnetic field. This magnetic excitation has essentially two components (appendix IV of reference 5). The first is that of induction which varies directly with the current and inversely as the square of the distance from the source. The second is that of radiation which not only varies directly with the current but also with frequency, and inversely as the first power of the distance.

In the case of the normal beacon receivers, the wave length is of the order of 1,000 meters, and the distance of equality between the magnetic components of the induction and radiation fields is approximately 159 meters. At distances of the order of 10 to 50 feet from the source of interference, the radiation component of the magnetic field would then be expected to have a value of the order of two to ten per cent of that of the induction component. The shielded loop will respond to this resultant magnetic field even though it is weak, and at short distances, the response will be preponderantly to the induction component. The strength of interference pickup in the shielded loop should then vary almost exactly as the inverse square of these short distances from the interference source.

The problem of reducing the interference pickup of the shielded loop is then primarily one of removing the source of disturbance as far as possible from the loop, taking advantage of the inverse square law, and of reducing as much as possible the amplitude and wave front of the individual current impulses in the discharges.

Control of Electrical Discharges From Aircraft

Since it is apparently impossible to prevent the accumulation of electric charges during flight through certain storm conditions, corona discharges from extremities of the aircraft must of necessity occur when the potential differences between these extremities and the surrounding atmosphere become sufficiently high. It has been shown that these discharges will produce interference in the normal-frequency radio receiving equipment on board the aircraft unless they are so controlled as to prevent the appearance of random, steep-wave-front current impulses.

A conductor trailing or projecting from the tail of the airplane and terminating in one or more sharp, slender points would be expected to discharge considerable energy to the region immediately surrounding the points. It has been shown that such sharp, slender points produce discharges, regardless of polarity, which for low and intermediate values of current are free from the disturbing current impulses.[5] To guard against interference from other types of discharges which might form in the vicinity of these points, it would be well to supply the trailing or projecting conductors with resistive and inductive wave-front suppressors.

For extremely large airplanes and for conditions of flight through severe storm areas, a single trailing conductor does not provide adequate discharging capacity. In those cases it would be desirable to have point dischargers of the sharp, slender variety, with resistive and inductive wave-front suppressors, on the wing tips and probably also on the nose of the airplane. The wing tip electrodes, and also possibly other discharge points at the extremities of the vertical and horizontal fins, might be of either a trailing or projecting type. Other sharp projecting edges and points on exposed parts of the airplane then should be carefully removed.

The end to be worked toward is that of allowing sufficient energy to be discharged from the controlled points to keep the potential of the plane low enough, with respect to the surrounding atmosphere, to prevent discharges from occurring elsewhere. This end might be attained not only by means of simple discharge points but also by the creation of intense primary ionization at these points. The discharge of a highly ionized liquid at the points, a relatively low-voltage d-c arc or a high-voltage, radio-frequency arc would serve to suppress the current impulses and eliminate the accompanying radio interference. Such procedures are necessarily more or less complicated and should be avoided if possible.

Exposed, normally insulating surfaces such as windshields and deicer boots can be made electrically conducting, and thus the accumulation of sufficient charge on such surfaces to cause sparking over to metal supports can be prevented.

Conclusion

Some of the results of this investigation already have been incorporated in emergency discharging devices installed on the transport airplanes of at least one of our major commercial airlines. The results obtained from this rather simple device have been very gratifying. The incorporation on a test airplane of all the numerous results and suggestions outlined in this paper would entail a great amount of time and expense. The problem eventually must be solved if the progress of aerial navigation is to continue. It is to be hoped that through active cooperation of all interested agencies this solution will be reached in the not-too-distant future.

A Wide-Band Square-Wave Generator

E. H. B. BARTELINK
ASSOCIATE AIEE

Synopsis: A square-wave generator is described which covers a very wide frequency range, is compact, self-contained, and adaptable to many other uses besides the investigation of transient response. The instrument uses a positive-bias type multivibrator. The operation of the multivibrator and clipping circuits are explained. Approximate formulas for the multivibrator frequency and pulse width are derived and discussed and its increased stability against interference explained. Methods and fields for application are then discussed.

FOR many purposes in communication work a square-wave generator delivering "square" voltage waves of variable frequency and "pulse width", is a valuable instrument. It can be used for testing and adjusting of complete telegraph, telephone, radio, and television channels, or of part of such channels, such as filters or amplifiers. The considerable distortion, produced in a square wave, by even small amounts of phase distortion makes it an ideal instrument for use in testing and aligning television circuits. In power circuits it can be used to determine the response of lines, transformers, and other components to unit step voltages.

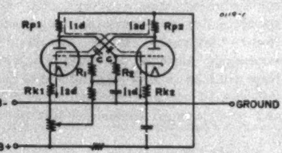

Figure 1. Positive-bias multivibrator

In all these cases the response can be viewed directly and thus immediate correlation with the results of unit step calculations is obtained. Given a wide frequency range of the square-wave generator and an independent scanning frequency in the oscillograph, it is possible to study either coarse or fine structure of the response. The constant repetition of the phenomenon permits photographic registration.

The following describes a square-wave generator, developed for these purposes. It has a very wide frequency range (approximately 2 to 200,000 cycles per second) a variable "pulse width" and is completely self-contained.

Description

A multivibrator is used as the oscillator in this instrument, its operation will be discussed in the next section. The output of this multivibrator is "clipped" in a following limiter stage and delivered into a low impedance (1,000 ohms) by a buffer tube. The anode voltage for these circuits is provided by a built-in, regulated power supply.

The multivibrator is of the positive-bias type, in which a variable positive bias, applied to the grid resistors, controls the frequency. This circuit offers the advantage of giving a very wide variation in frequency for the same set of circuit constants, while it greatly reduces the change of pulse width with frequency in each range. Furthermore, at higher values of the positive bias a much greater stability against external interference is obtained. The use of a regulated power supply results in a high stability against frequency drift, a representative figure being 13 cycles per second in 13,000 cycles per second over a ten-minute period, measured after the instrument had reached temperature equilibrium.

Due to the fact that a multivibrator is used, this square-wave generator can be synchronized from low-level external signals, which can be applied to a low-impedance input. The synchronization can be in a 1:1 ratio, but the instrument will also synchronize in multiple or submultiple ratios. These properties make it especially suitable for measurements of deflection linearity in television and oscilloscope time bases. Addition of a discharge circuit makes the instrument into a saw-tooth generator for oscilloscopes, while by cascading several square-wave generators, frequency division or multiplying chains (electronic gears) can easily be built up.

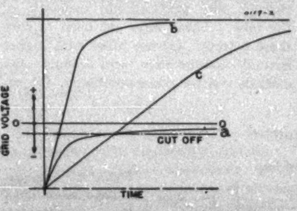

Figure 2. Multivibrator grid characteristics

Operation

The operation of "normal" multivibrators has been described by several authors and it can thus be treated very briefly. Fundamentally it is a two-stage resistance-capacity coupled amplifier, in which the input and output are directly interconnected. Oscillations will thus occur in the circuit. The frequency of these is chiefly determined by the *R* and *C* values used in the grid circuits of each tube; the flywheel effect, which carries the circuit over its dead points, is provided by the unavoidable inductances in the circuit wiring and the grid input capacities of the tubes. This oscillation produces such high voltages that, in alternation, the grid circuit of one of the tubes is pushed beyond its cut-off value and the amplification in this tube is reduced to zero. Therefore, the picture of a two-stage amplifier in which in- and output are interconnected, holds only during the very short "flip-over" or reversal time when both tubes amplify.

At every "flip-over" of the multivibrator operation, the grids are charged to a high negative voltage. This charge then leaks off along an exponential till the grid voltage attains cutoff. The tube then becomes conducting and the multivibrator again reverses or "flips over".

Let us now connect the grids to a point of positive bias, as shown in figure 1. Then—in the absence of grid and plate current in the tube—the grid would discharge along another exponential, until it had reached the higher positive voltage to which it was biased. As can be seen from figure 2, curves *a* and *b*, the part of the exponential between the starting point and the intersection with the cutoff voltage, constitutes a smaller part of the total voltage variation as we increase the positive bias. This results in two effects: (*a*) the time required for the grid to attain the cutoff value is reduced as the positive bias is increased, (*b*) the difference between this part of the

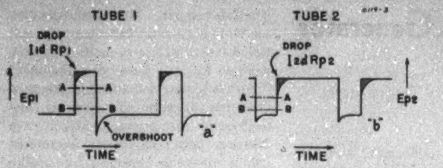

Figure 3. Plate-voltage wave forms in unsymmetrical multivibrator

exponential and a straight line is decreased, that is, the steepness of the grid-voltage curve is increased at the cutoff point.

The first effect results in an increase in frequency with increased bias, the second one results in reduced sensitivity to interference with increased bias. Both effects will be discussed in more detail. The frequency range that can be obtained with any one set of circuit components is large; it is in the order of 10:1. Thus, with two ranges for every 10:1 increase in frequency, a wide overlap of the ranges can be obtained.

This type of frequency control has the practical advantage of being a d-c control and as the frequency control does not carry any signal currents it can be placed at any distance from the oscillator circuit.

The voltages appearing on the multivibrator plates have the forms shown by figures 3*a* and 3*b*. It is easy to see that at least two clipping operations are necessary to obtain a square output from these waveforms. First the part above *AA* has to be clipped off. For a fixed frequency this can easily be done. For a variable frequency however, we find that the curved part occupies a varying fraction of the peak-to-peak swing and this fraction can easily go up to 70 per cent. To ensure a good clipping action under these conditions we have to either reduce the frequency range per set of circuit constants; introduce more than two stages of clipping; or have an instrument that is very critical in adjustment.

All these objections were overcome by inserting resistors in the cathodes of each multivibrator tube. These cathode resistances are shown in figure 1. The wave form on these resistors is as shown in figures 4*a* and 4*b*. A single clipping operation which removes the part above *CC* would convert this into a square wave, but the polarity of the signal makes it impossible to obtain this clipping by pushing the grid of a tube beyond cutoff. This was circumvented by connecting the cathodes of the clipper and one of the multivibrator tubes together and grounding the clipper grid.

Adjustment of the clipping point was done by changing the screen-grid voltage. This "upside down" operation of the clipper has proved very satisfactory. It provides a positive pulse in the anode circuit; this can be directly fed to the grid of the buffer tube. The interstage coupling was designed for wide-band operation and carefully adjusted for low-frequency phase shift. A high-frequency "peaking" inductance can be added to good advantage for equalizing the high-frequency to the midband response.

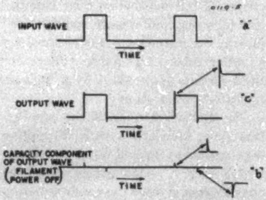

Figure 5. Wave forms in cathode output circuit

The buffer circuit is of the conventional cathode output type and delivers five volts in 1,000 ohms. At high frequencies "peaking" distortions which produce overshoots of the edges, can occur in such a buffer circuit due to the coupling through the grid-cathode capacity of the tube. Three ways are open to cure these defects: (*a*) use tubes with higher mutual conductance and reduce the cathode resistor correspondingly, (*b*) reduce the driving voltage as much as is compatible with a reasonable safety margin (for instance 30 per cent) for clipping, (*c*) put some parallel capacity in the driving circuit to reduce the slope of the driving wave form. Using these methods good wave forms are obtainable even at high frequencies.

At frequencies near the top frequency of operation where a high number of harmonics cannot be produced by the multivibrator, the output wave form rounds off, as is to be expected.

In order to increase the frequency range in which these effects are unnoticeable, proper care should be taken to obtain good high-frequency response in the multivibrator circuit. This includes short leads, reduction of the loop area of the circuits, and reduction of the capacity between grid and plate circuits to the same tube.

Multivibrator Frequency

In connection with the positive-bias-type multivibrator, it is interesting to investigate which factors determine the multivibrator frequency and pulse width. It is well known that a rigorous analysis requires solution of the nonlinear differential equation, as treated by van der Pol (*Phil. Mag.*, volume 11, 1926, page 478, and other places).

Some of the important properties of a multivibrator can, however, be determined without recourse to a nonlinear treatment. While the results necessarily must be an approximation, they will lead to an understanding of the influence of circuit constants, tube gain and grid bias on frequency and pulse width. As a by-product they give a fairly simple formula for the multivibrator frequency which seems to be a much closer approximation than the handbook formula: $f=1/rc$

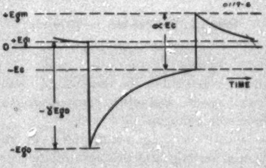

Figure 6. Grid-voltage wave form of multivibrator

We introduce the following symbols, which are partly illustrated in figure 6

E_g = instantaneous grid voltage
$+E_a$ = anode supply voltage

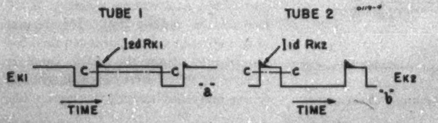

Figure 4. Cathode-voltage wave forms in unsymmetrical multivibrator

$+E_{gb}$ = grid (bias) supply voltage
$+E_{gm}$ = initial (or maximum) positive grid voltage after a positive "flip-over"
$+E_{gt}$ = positive grid voltage just before a negative "flip-over"
$-E_c$ = cutoff voltage of the amplifier tube
$-E_{g0}$ = initial negative grid voltage after negative "flip-over"
$\alpha = \dfrac{E_{gm}+E_c}{E_c}$ = "overswing ratio" in positive direction
$\gamma = \dfrac{E_{gt}+E_{g0}}{E_{g0}}$ = "overswing ratio" in negative direction
$\beta = E_{gb}/E_a$ = bias ratio
G = absolute value of the stage gain if one of the multivibrator tubes is used as a straight amplifier
$r = R_g+R_p$ = total discharge resistance (for most practical cases we may put $r=R_g$)
C = grid to plate coupling capacitor

In the region where the grid voltage is below cutoff, it is given by:

$$E_g = E_{gb}-(E_{gb}+E_{g0})\epsilon^{-\frac{t}{rc}} \tag{1}$$

"Flip-over" occurs as soon as the grid obtains the cutoff value, thus when:

$$E_g = -E_c \tag{2}$$

The cutoff voltage (in triodes) depends on the anode voltage and the amplification factor μ of the tube and is given to good approximation by:

$$E_c = +\frac{E_a}{\mu} \tag{3}$$

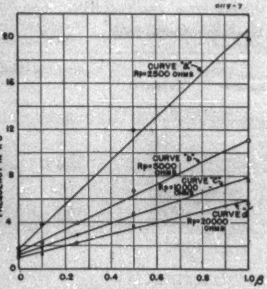

Figure 7. Frequency characteristics of positive-bias multivibrator

The initial grid swing is determined by the grid swing in the preceding tube, which is αE_c and by the gain G from this grid into the next grid. On this next grid it is $-\gamma E_{g0}$ by definition. Thus in a linear system we would have:

$$-\gamma E_{g0} = -G\alpha E_c \tag{4}$$

Now assume that the gain during the "flip-over" period is constant and equal to G and that the ratio $\delta=\alpha/\gamma$ is also a constant.

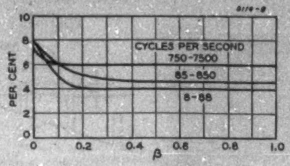

Figure 8. Pulse-width characteristics of positive-bias multivibrator

These simplifying assumptions reduce the problem from a nonlinear to a linear one. As mentioned above, we know that this constitutes an error because in at least the regions near cutoff or those of small positive grid bias, the tubes are nonlinear. Consequently we will never be able to determine the ratio δ, the effective gain or the relation of anode voltage and frequency from our calculation, but the result does give us an insight in the effect of different parameters on frequency and pulse width.

Now, substituting (3) in (4) we find:

$$E_{g0} = \delta/\mu G E_a \tag{4a}$$

Substituting $E_{gb}=\beta E_a$ (from the definitions) and equation 4*a* into (1) this becomes:

$$E_g = \beta E_a - \beta E_a\left(1+\frac{\delta G}{\mu\beta}\right)\epsilon^{-\frac{t}{rc}} \tag{5}$$

"Flip-over" occurs when E_g attains the value

$$E_g = -E_c = -\frac{E_a}{\mu}$$

Substituting this into (5) E_a drops from the formula and we can determine the time t_0 between two trippings. From it, we find for the time during which the grid remains below cutoff in a symmetrical multivibrator:

$$t_0 = rC\cdot \log_e\left(\frac{\delta G+\mu\beta}{1+\mu\beta}\right) \tag{6}$$

where $\log_e$ represents the natural logarithm and for the frequency of the multivibrator:

$$f_0 = \frac{1}{2\cdot rC\cdot \log_e\left(\dfrac{\delta G+\mu\beta}{1+\mu\beta}\right)} \tag{6a}$$

To obtain a real, positive value for t_0, the effective gain, including overshoot, must exceed unity. Decreasing gain leads to increased frequency. This is in accordance with the general behavior of multivibrators and we might thus expect a better approximation from (6) than from the handbook formula which does not contain the gain or the bias at all. The results given in tables I and II for the case of zero grid bias check this, but secondary effects may under circumstances reverse these conditions.

The absence of E_a from (6) shows agreement with the fact, that in most of the actual multivibrators tested, its influence on the frequency rapidly decreases for values of E_a above approximately 100 volts.

As explained, the ratio δ cannot be determined from the analysis. From observations, made on a number of multivibrators, it seems justified to assume a range of approximately 1.0 to 3.0, with a most probable value of 1.50.

Special Cases

We now consider special cases of formula (6).

1. For zero value of the bias ratio we find:

$$f_0 = \frac{1}{2\cdot rC\cdot \log_e(\delta G)} \tag{6b}$$

2. For very small values of β, for which $\mu\beta << 1$ the development for $\log_e(a+x)$ gives:

$$f_0 = \frac{1}{2\cdot rC\cdot \log_e(\delta G)}\left\{1+\frac{\mu\beta}{\delta G}\,\frac{\delta G-1}{\log_e(\delta G)}\right\} \tag{6c}$$

3. For high values of β we soon approach the case where the positive bias voltage is large compared to the initial grid voltage. We then operate on the steep initial part of the exponential and can stop the development for $\epsilon^{-t/rc}$ after the second term, thus:

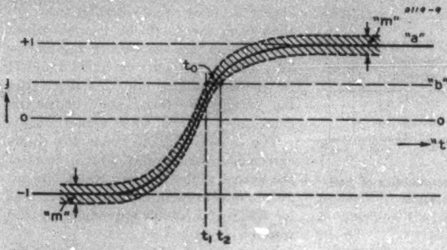
$$f_0 = \frac{1}{2\cdot rC}\cdot\frac{1+\mu\beta}{\delta G-1} \tag{6d}$$

We see that for higher values of the bias ratio the multivibrator frequency should vary linearly with the bias ratio. From (6*c*) and (6*d*) we can derive the steepness $\delta f/\delta\beta$ of the frequency characteristics for low and high bias ratio, thus:

$$\left(\frac{\delta f}{\delta\beta}\right)_{lo-\beta} = \frac{\mu}{2rC}\cdot\frac{1-\dfrac{1}{\delta G}}{\log_e{}^2(\delta G)} \tag{6e}$$

$$\left(\frac{\delta f}{\delta\beta}\right)_{hi-\beta} = \frac{\mu}{2rC}\cdot\frac{1}{\delta G-1} \tag{6f}$$

Comparing the steepnesses of (6*e*) and (6*f*) for different values of δG we see that for values ranging from 1.3 to 10 the ratio between the two steepnesses varies from 1.02:1 to 1.50:1. Thus there is only a small difference in the steepness between low and high values of the bias ratio. We might therefore expect that the frequency will vary nearly linearly, not only over the range of high values of the



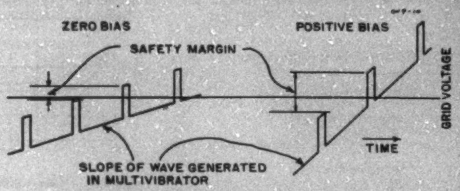


Figure 9 (left). Influence of interference on time of "tripping"

Figure 10 (above). Grid-voltage wave forms in electronic-gear operation

bias ratio, but throughout the whole range.

Reference to figure 7*a*, *b*, *c*, which gives some representative cases, shows that this conclusion is very well confirmed by the experiment. Thus formula (6) has allowed us to correctly deduce the character of the frequency versus bias characteristic. This linear relation of frequency and bias opens a wide range of applications for the positive bias type multivibrator.

Pulse Width

In many cases it is important to have a wave of variable frequency but approximately constant pulse width. With the preceding formulas we determine the pulse width as defined by

$$\lambda = \frac{t_{01}}{t_{01} - t_{02}} \tag{7}$$

where t_{01} and t_{02} represent the times during which grids 1 and 2 have been driven below cutoff.

Assume that the multivibrator uses two tubes of the same type and that their plate loads, and therefore their gains are equal. We then derive from (6)

$$t_{0k} = r_k C_k \cdot \log_e \left(\frac{\delta G + \mu\beta}{1 + \mu\beta} \right) \tag{7a}$$

where k can be 1 or 2. Substituting this in (7) we find:

$$\lambda = \frac{r_1 C_1}{r_1 C_1 + r_2 C_2} \tag{7b}$$

and deduce that the pulse width should be independent of the bias-setting and thus independent of the frequency. Figure 8 shows that this checks reasonably well; the change in pulse width for the three multivibrators shown, amounts to 20–50 per cent of the initial value, for frequency changes in a ratio of 10:1. Nearly all of this change occurs at low values of β ($\beta < 0.20$).

Interference

Consider an electrical circuit, which performs a certain operation as soon as the driving voltage or current in a certain control circuit attains a prescribed "critical" value. Let the voltage or current be a recurrent, periodic phenomenon which can be either impressed from outside or generated in the circuit itself.

In the absence of interference the circuit will then operate at exactly equal time intervals, that is, at constant frequency.

The multivibrator is an example of the second (oscillator) type circuit which provides its own driving voltage and has the tube cutoff as the critical value.

In figure 9 curve *a* represents the control-circuit driving voltage or current; *y* is its instantaneous value expressed as a fraction of its peak to peak swing; the center between peaks is used as zero or reference level; *b* is the critical value, and t_0 the time at which the operation is started.

Tables I, II, III: Comparison of Previous Formula (F_0) for Multivibrator Frequency With New Formula (f_0) and Observed Frequency (f)

I. Zero Bias—Test Multivibrator

Gain	$F_0 = \frac{1}{rC}$	$f_0 = \frac{1}{2rC \log_e (\delta G)}$	f observed	Error (Per Cent) In F_0	Error (Per Cent) In f_0

Figure 12. General Electric square-wave generator

Now consider the case where interference is present. Let the peak-to-peak value of the interference be a fraction m of the ptp swing, it may have any arbitrary wave form. Thus the effective driving voltage may have any value within the shaded area in figure 9. The operation may thus be started at any moment between t_1 and t_2 and the time of operation has an "uncertainty region" $\Delta t = t_2 - t_1$. Defining the slope of the undisturbed driving voltage as $s = dy/dt$, we find from the figure $s = dy/dt = m/\Delta t$ and

$$\Delta t = \frac{m}{s} \tag{8}$$

This relation is well known in telegraph communications (to the author's knowledge it was first clearly stated by Doctor H. Salinger, Documents, *CCIT*, 1926, pages 7–9) and shows that the uncertainty region is inversely proportional to the slope.

As can be seen from figure 2, curves *a* and *c*, the application of positive bias to a multivibrator will considerably increase the steepness of the grid voltage curve at the intersection with the cutoff value; for high bias values the steepness of the cutoff value practically equals the initial steepness. Thus the sensitivity to interference should be reduced. To check this an erratic interference was applied to a zero-bias multivibrator and increased in amplitude till the uncertainty zone covered 50 per cent of one cycle. This means that the operation had become so irregular that a fundamental frequency could no longer be recognized. Changing the same multivibrator to positive bias and readjusting the grid capacitors to obtain the same frequency the uncertainty zone was reduced to 8 per cent for the same amount of interference voltage.

This increased stability is particularly important to television systems where the multivibrator may be used as a time base. The increased steepness will also be an advantage in maintaining the proper frequency division at high-frequency ratios, as they may be encountered in pulse generators for television. Figure 10 demonstrates this point by showing the increase in safety margin obtained by increasing the slope of the grid characteristic.

Circuit Components

Further analysis leads to some practical conclusions on the choice of circuit components.

To obtain a large frequency range, the grid-leak resistors should be chosen as high as is compatible with safe operation of the tube. Failure to observe this, will—through grid rectification—result in a lowering of the voltage on the grid decoupling capacitor which counteracts the increase in bias.

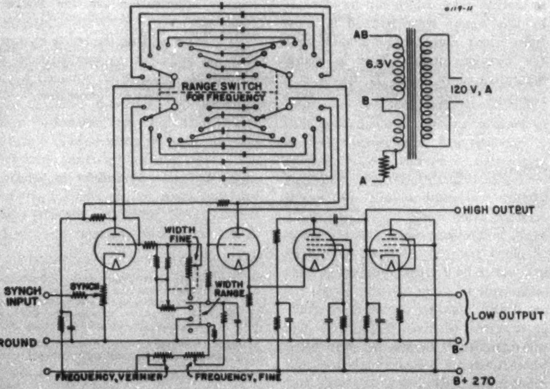

Figure 11. Circuit diagram of square-wave generator

Equal grid capacitors should be used if independence of the pulse width from the frequency is desired. During the "flipping over" part of the cycle, the grid coupling capacitor is connected between the plate of one tube and the low-impedance of the conducting grid-to-cathode path of the other tube. Its impedance determines the voltage transferred to the grids and if these capacitors are unequal, the ratio of the grid peak voltage will change with frequency. This will result in changing pulse width.

General Data

The whole instrument is mounted on a standard 19-inch relay rack panel. The panel height is $8^3/_4$ inches, the depth behind the panel is 13 inches. The controls on the front panel are: synchronizing amplitude, width (fine), frequency-range, width-range, frequency (fine), frequency (vernier).

The diagram is given in figure 11, the outside appearance is shown in figure 12.

Application

There is such a variety of problems for which the square-wave-generator can and has been used, that we cannot attempt to give an adequate review of them within the scope of this paper. Rather than that we will give some typical examples (two on amplifiers, one on transmission lines) from which the advantages of the method can easily be seen.

These advantages become clear if we realize, that the transient response, resulting from a unit-step voltage, in-

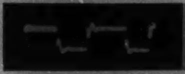

Figure 13. Response of LCR network—low damping

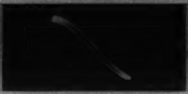

Figure 17. Lissajous figure for the network of figure 6

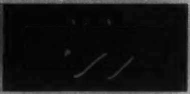

Figure 18. Effect of overload in amplifier on square-wave response

volves the complete amplitude and phase response of the circuit in consideration. Thus one single measurement with square waves can give us an amount of information, which we could otherwise only obtain by the laborious process of determining the complete amplitude and phase response curves as a function of frequency.

As a first example we show some oscillograms of the square-wave response of a wide-band amplifier, in whose plate circuit a series connection of L, C, and R was branched across the plate resistor. In order to demonstrate the results which can be obtained with even very simple equipment, a standard three-inch oscilloscope and a normal camera was used when these and the following oscillograms were photographed. The use of a larger oscilloscope will, of course, give the advantage of finer detail in the oscillogram.

In figure 13 the response is shown when a square wave of approximately 50 per cent width and a frequency of approximately 10 kilocycles is applied to the circuit. We can directly deduce from this one measurement that an oscillatory transient of approximately 60 kilocycles is present in the system. In any actual problem this result would tell us where to improve the circuit. Figures 14 and 15 show the effect of increasing the series resistance in this *LCR* branch.

In figure 16 the use of the square-wave generator to detect low-frequency phase shift is demonstrated. The presence of this phase-shift is shown by the "sloping off" of the top part of the narrow pulse and by the base line or "floor" of the pulse being at different levels before and after occurrence of this narrow pulse. Analysis will show that sensitivity of measuring phase which can be obtained by this square wave method is many times larger than that obtainable with the Lissajous figure. This is clearly demonstrated in figure 17 which is a Lissajous ellipse for the same phase shift as was used in figure 16 and for approximately equal deflection amplitudes on the oscilloscope screen. As can be seen the ratio between short and long axes of the ellipse is considerably smaller than that between the dropping-off of the pulse top and the pulse height. Figure 18 demonstrates what happens if overload occurs somewhere in the amplifier. In this case the leading and trailing edges of the pulse have different magnitude. This effect can, for instance, be caused by grid current on the amplifier, which grid current occurs at a swing of positive polarity on this grid and is absent during a negative swing. The responses to positive and negative unit-step voltages are then different as result of the rectification occurring in the grid.

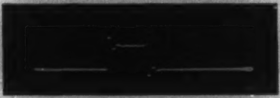

Figure 19. Response of improperly terminated transmission line

Square-wave input in transmission line terminated in pure resistance 25X characteristic impedance; observed at end of line

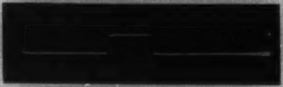

Figure 20. Response of properly terminated transmission line

As case 19, but terminated in characteristic impedance

In figure 19 an example is given of the transients set up in a transmission line, if it is not terminated in its characteristic impedance. The stepping up of the voltage due to excessive termination resistance is clearly visible. Using a decade box, the proper termination was immediately found by adjusting it until the square wave of figure 20 was observed. Determination of this characteristic impedance would have taken considerably more time by conventional methods and not yielded the comprehensive information on the transient response.

It is expected that the above examples may be sufficient to demonstrate the advantages that can be obtained by the use of the square wave generator.

Harmonic-Current-Restrained Relays for Transformer Differential Protection

C. D. HAYWARD
ASSOCIATE AIEE

DIFFERENTIAL protection, employing percentage-differential relays, has[1] long been the accepted method of fault protection for large power transformers. This method, illustrated by the schematic diagram, figure 1, is quite satisfactory in most respects but is subject to false tripping on the transient magnetizing-inrush current which flows when the transformer is energized. This current, since it flows in only one winding of the transformer, causes a differential current to flow which, to an ordinary relay, "looks" the same as the current due to an internal fault. One method of preventing operation on magnetizing inrush in the past has been to use slow-speed induction-type relays with long time and high current settings. This is undesirable because of the slow-speed, insensitive protection it affords on internal faults. Other methods, applied to high-speed relays, involve desensitizing the relay during a time period covering the maximum inrush transient controlled by auxiliary relays operating on the transformer voltage.[2] These methods have the disadvantage that they usually require the purchase of additional potential transformers, involve one or more auxiliary relays with the attendant circuit complication, and seriously reduce the sensitivity of the protection against faults present when the transformer is energized or which occur during the inrush period. In this paper a new type relay is described which, using the principle of harmonic-current restraint,[3] is able to distinguish between the differential current due to an internal fault and that due to magnetizing inrush by their difference in wave form, operating with high speed on the fault current and being restrained from operating by the magnetizing-inrush current. Being entirely current-operated, this relay does not require the purchase of potential transformers. It is entirely self-contained and the only moving part is the single relay armature which operates the tripping contacts. Minimum desensitization during the inrush period is obtained, depending on the relative magnitudes of the inrush and the fault currents.

PERCENTAGE DIFFERENTIAL RELAY

Figure 1. Schematic one-line circuit diagram showing percentage-differential relay protection of a two-winding power transformer

Current may also flow in the differential circuit when no internal fault is present, due to saturation of the current transformers on heavy through faults causing ratio breakdown of differing amounts in the two transformers. The tendency to operate on this current is successfully restrained by the through-current restraint of the ordinary percentage-differential relay. Since the wave form of this current is nonsinusoidal it might seem that harmonic restraint could be used to prevent operation on it, too, and the through-current restraint eliminated. While the harmonic restraint does aid in this, and while it might be used alone in some cases, in general the through-current restraint is needed for two reasons: first, nearly all large modern power transformers are equipped with load-ratio control. As the transformer ratio is changed the ratio between the primary and secondary current-transformer ratios can be made to match it at only one point of the tap-changing range. At other points an unbalance current will flow in the differential relay. On normal load and on low-current through faults this unbalance current will have essentially sine wave form, hence the harmonic restraint cannot distinguish it from the current due to a small internal fault. Second, in many cases, particularly on wye-delta transformer banks, it is necessary to connect at least one set of the current transformer secondaries in delta. On balanced three-phase through faults, and to some extent on other faults, the third-harmonic component will circulate in the delta and will not appear in the differential relay current. This does not occur for the second, fourth, and fifth harmonics, so that adequate restraint can be obtained on differential currents containing liberal proportions of one or more of these. This effect does not occur even for the third harmonic when the current transformer secondaries are all wye-connected.

Figure 2. Type HDD11A percentage-differential relay with harmonic-current restraint for two-winding transformer protection

Harmonics

Any current of nonsinusoidal wave form ordinarily encountered in electric circuits may be considered as being composed of a direct-current component plus a number of sine-wave components of different frequencies; one of the fundamental line frequency of the circuit and the others harmonic multiples—two, three, four, five, etc., times the fundamental frequency.[4] The relative magnitudes and phase positions of the fundamental and the various harmonic components determine the wave form. Harmonic analyses of typical differential-current wave forms due to magnetizing inrush and due to current transformer saturation on heavy symmetrical through-fault current are shown in table I. These are expressed in terms of relative crest values with the fundamental component taken as 100 per cent.

The current - transformer - saturation wave analyzed, being due to a symmetrical fault current, is itself symmetrical and hence contains only odd-numbered harmonics. The wave for an offset fault current would be asymmetrical, containing direct current and even-numbered harmonics as well as the odd ones.

Table I. Harmonic Wave Form Analysis

	Typical Differential Current Wave Due to:	
Wave Component	Magnetizing Inrush (Per Cent)	Current Transformer Saturation (Per Cent)
Fundamental	100.0	100.0
Direct current	57.7	0.0
Second harmonic	63.0	0.0
Third harmonic	26.8	37.4
Fourth harmonic	5.1	0.0
Fifth harmonic	4.1	16.7
Sixth harmonic	3.7	0.0
Seventh harmonic	2.4	7.8

Briefly speaking, in the harmonic-restrained relay, the fundamental-frequency-current component tends to operate the relay while the harmonic components tend to restrain it. Operation occurs on waves having less than the percentage of harmonics for which the relay is set and is restrained on waves having more than this amount.

Relay Circuits

A percentage-differential relay with harmonic restraint, intended for the protection of a two-winding transformer, is shown in figure 2. The internal circuits of this relay are shown schematically by the diagram, figure 3. Referring to this diagram, it will be seen that the current enters the relay through two small auxiliary current-transformers mounted inside the relay case. One of these has its primary coil connected in the differential circuit and the other has two primary coils, one of which is connected in each of the main current-transformer circuits. These two coils are wound in such relative direction that their magnetizing effects are additive on through-fault currents. The coils on both transformers are tapped to allow approximate matching of the power-line current-transformer ratios. The tap leads are brought out to a double tap-block by means of which the number of turns through which the current flows is changed simultaneously on both transformers when the tap plug is moved from one position to another, maintaining a constant ratio and hence a constant through-current per cent slope characteristic.

RELAY THROUGH CURRENT TRANSFORMERS

Across the secondary of the differential-current auxiliary transformer two parallel circuits supplying the relay element are connected. One of these circuits includes the operating coil of the relay and is tuned to pass currents of the fundamental power-system frequency and to offer high

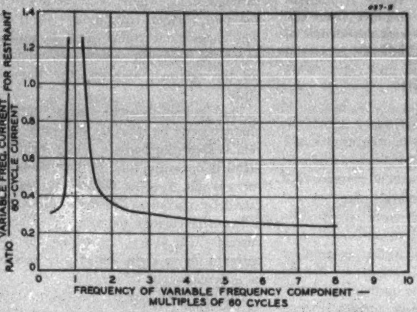

Figure 5. Harmonic-restraint versus frequency characteristic of harmonic-restraint relays

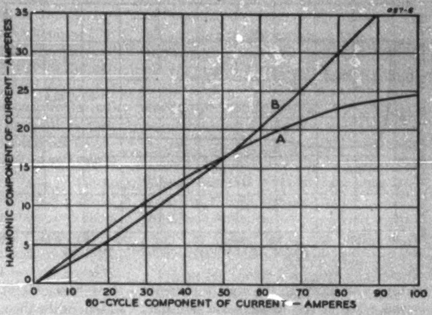

Figure 6. Harmonic-restraint versus current characteristics of harmonic-restraint relays

Curve A—Magnetizing-inrush type wave having predominant second harmonic

Curve B—Current-transformer-saturation type wave having predominant third harmonic

impedance to currents of other frequencies. The other circuit, including the restraining coil of the relay, is tuned to block system-frequency currents and to pass currents of harmonic frequencies. This circuit also includes a rectifier for smoothing the restraint magnet pull. The per cent of harmonic current required is adjusted by means of the shunting resistor R_3.

The d-c component present in the differential current is blocked by the differential-current transformer which is equipped with an air-gap core for this purpose. Only a small part of it appears in the secondary circuit and this divides between the operating and restraint circuits, producing little effect either to operate or to restrain the relay. Elimination of the d-c component prevents the saturation of the reactors L_1 and L_2 with consequent detuning of the filter circuits which would occur if it were allowed to flow.

A Thyrite resistor connected across the relay differential-current transformer secondary serves to limit the peak value of momentary voltage "kicks" which sometimes occur due to shock current excitation of the tuned circuits. These voltage peaks, if not limited, would be likely to puncture the rectifiers or capacitors. The time duration of the voltage peaks is so short and, due to the nonlinear resistance characteristic of the Thyrite, the current passed through it by the lower voltages present at other times is so small that the operation of the relay is not appreciably affected.

The secondary of the through-current transformer also supplies current to the restraining coil through a second rectifier. This transformer also has an air-gap core for elimination of the d-c component. A shunting resistor R_1 with taps brought out to a tap block provides adjustment of the per cent slope of the through-current restraint characteristic.

For three-winding power-transformer protection, a relay having the through-current restraint circuits modified as shown in figure 4 is provided. Three independent through-current-restraint auxiliary transformers, one for each of the three line-current-transformer circuits, are provided. Each auxiliary transformer has its secondary winding connected through an independent rectifier to the restraining coil of the relay. This arrangement allows complete freedom as to location of power sources and loads on the three windings of the power transformer, maintaining a constant per cent slope independent of the relative directions of current flow in the three windings.

Construction and Characteristics

The two-winding transformer relay, type *HDD11A*, is mounted in the standard $5^1/_2$ by 16-inch universal relay case, as shown in figure 2. The three-winding transformer relay, type *HDD11B*, is also mounted in the $5^1/_2$ by 16-inch case and has the same external appearance except that where, in the two-winding relay, two horizontal rows of tap positions are provided for matching the ratios of the current transformers in the two winding circuits, three rows are provided in the three-winding relay. Eight current taps are provided in each relay having nominal ratings of 2.9, 3.2, 3.5, 3.8, 4.2, 4.6, 5.0, and 8.7 amperes.

The relay element is of hinged-armature construction. Two electrically-separate single circuit-closing contacts are provided, with an electrically-operated target in series with one of them.

The differential burden imposed on the current transformers by the 60-cycle relay is 16.0 volt-amperes, 12.5 watts, measured at 5.0 amperes on the 5.0 ampere tap. The through-current burden on each current transformer is 1.2 volt-amperes, 1.0 watts measured in the same way. These burdens vary inversely as the square of the tap current rating for other taps but are substantially independent of the per cent slope setting.

The minimum pickup on sine-wave rated-frequency current, is 1.0 ampere. This is with the tap plugs in the 5.0 ampere and 25 per cent slope positions. This value varies directly with the tap current rating and is slightly higher for the 40 per cent slope, lower for the 15 per cent slope positions.

The harmonic-restraint versus frequency characteristic curve in figure 5 illustrates the selective action of the relay filter circuits. This curve was obtained by mixing two currents in the relay, one of 60-cycle frequency and the other of a frequency which was held at a number of different values varying over a range of from 25 to 480 cycles. At each point the variable-frequency current was held at ten amperes and the 60-cycle current increased until the relay operated.

The harmonic-restraint versus current characteristics in figure 6 were taken under conditions more closely simulating those of actual service. Curve *A* was taken with a current wave approximating the magnetizing-inrush form. This current was obtained from a small saturating reactor, polarized with direct current in another winding. Sine-wave 60-cycle

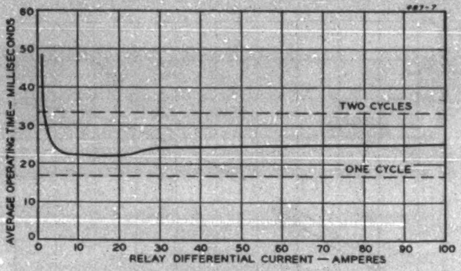

Figure 7. Operating-time versus current characteristic of harmonic - restraint relays

current was added to the reactor current in the relay in the same phase position as the 60-cycle component of the reactor current. The relative proportions of the two currents were adjusted to obtain a series of values at which the relay operated. The magnitudes of the fundamental and second-harmonic components were read with a special harmonic current meter. These two components were plotted against each other to obtain the curve. An attempt was made to operate the reactor in a saturation range giving as little third and higher harmonics as possible in order to isolate the effect of the second harmonic. The magnitude of the third harmonic measured as a check did not exceed eight per cent of the fundamental.

Curve *B* was obtained using the same reactor without the d-c polarization. This gave a current wave of the current-transformer-saturation type. In this case the magnitude of the predominant third harmonic was read and plotted against the fundamental.

The falling off of curve *A* as well as the rise in curve *B* is due to the exciting current taken by the relay differential-current transformer. This exciting current has a third harmonic component which increases in relative magnitude at the higher currents. In the case of the magnetizing-inrush or predominant-second-harmonic type wave used for curve *A* this exciting current subtracting from the differential current flowing in the primary of the relay differential current transformer leaves a third harmonic of reversed phase position in the secondary circuit which combines with the second harmonic in producing restraint. Hence, as the magnitude of the differential current is increased a decreasing proportion of second harmonic is needed in it to produce restraint. In the case of the current-transformer-saturation or predominant-third-harmonic type wave used for curve *B*, the third harmonic in the exciting current is in the same phase position as the third harmonic in the primary current so that when the exciting current is subtracted a reduced proportion of harmonic is present in the secondary circuit. This makes it necessary to have an increasing proportion of third harmonic in the differential current fed into the relay in order to obtain the constant proportion required to restrain the relay in the secondary circuit of the differential current transformer.

In the application of the relay the falling off of curve *A* is of no consequence since adequate restraint is provided for all magnitudes of magnetizing-inrush-current waves. The rise in curve *B* is definitely advantageous in that it gives a greater operating margin on high internal-fault currents, which contain a certain amount of harmonics due to current-transformer saturation. The percentage of harmonics present in the differential current due to an internal fault, where the currents from the two current transformers add, is less, of course, than in the case of the differential current due to a through fault, where the currents from the two current transformers subtract. The harmonic-restraint curve *B* lies between the harmonic percentages obtained for the internal fault and the through fault.

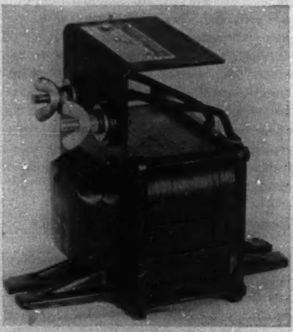

Figure 8. Portable saturating test reactor for adjusting harmonic-restraint setting of harmonic-restraint relays

The operating-time versus current characteristic on 60-cycle sine-wave current is shown in figure 7. The slight increase in operating time for the higher currents is due to some self-restraint introduced by partial saturation of the relay differential current transformer at high current. The average operating time for currents above eight amperes is seen to be approximately $1^1/_2$ cycles.

The through-current restraint slope characteristics are not shown since they are quite similar to those of other percentage differential relays. Taps for 15, 25, and 40 per cent slope are provided.

A means of checking the unbalanced differential current flowing in the relay on normal load is provided by two terminals, not shown in figures 3 and 4, connected to the secondary leads of the relay internal differential-current transformer. A high-resistance voltmeter momentarily connected to these terminals gives an indication of any unbalance current without disturbing the current connections of the relay.

Tests and Adjustments

The relay may be completely tested and adjusted on the switchboard by means of simple and readily portable equipment. The test circuits used for checking the minimum pickup current and the per cent slope or through-current restraint are the same as for any other percentage-differential relay and need not be described here.

For checking the harmonic-restraint setting of the relay a special saturating reactor is used. This reactor, illustrated in figure 8, is readily portable since it weighs only nine pounds. In use, the reactor is simply connected in series with the relay terminals to a 115-volt source of the rated frequency. The steady-state current passed has an rms value of ten amperes and contains a third-harmonic component whose magnitude is 25 per cent of that of the fundamental-frequency component. Under steady-state conditions, no even harmonics are present and higher odd harmonics are present only in negligibly small amounts. Normal line voltage variations do not appreciably affect the harmonic percentage of the reactor current because of a special core construction which holds the percentage constant within 1 per cent over a range of 105 to

125 volts, although the current magnitude varies. Variation in the harmonic percentage due to changes in the relay burden when the current transformer ratio-matching taps or the per cent-slope taps are changed is negligible. With the reactor current flowing in the relay, the harmonic-restraint adjusting resistor (*R*2 in figures 3 and 4) is varied until the relay armature is just on the verge of picking up.

Performance Tests

As "the proof of a pudding is in the eating", so the proof of a relay is in the quality of its performance under actual service conditions. A number of oscillograms illustrating the performance of the type *HDD*11*A* harmonic-restrained percentage-differential relay tested under conditions closely simulating those met in actual service are shown in figures 9*A*, *B*, *C*, *D*, and *E*. The only departure of any significance from typical service conditions in these tests lies in the size of the transformer used. The transformer to which the differential protection was applied in these tests was a single-phase 333-kva General Electric distribution-type transformer; type *H*, form *D*, 13,800/460 volts, 60 cycles. High-speed differential protection would not ordinarily be applied to a transformer as small as this. The only important effect this has on the results, however, is in the decay rate of the magnetizing-inrush current. In large transformers, the inrush current falls off at a much slower rate than it does in small transformers, in many instances remaining at values in excess of full-load current for a period of several seconds. The rate of decay in the transformer used, however, was sufficiently slow to illustrate the performance of the relay. The slower rate obtained with a larger transformer would only serve to make the need for harmonic restraint and its advantages over other methods of preventing false operation on magnetizing inrush more evident.

A type *KC*-58, 20/5-ampere current transformer was used on the 13,800-volt side of the transformer and a type *JW*-1, 600/5-ampere current transformer on the 460-volt side. These ratios were chosen so that the normal load secondary currents would exactly match. The current-transformer ratio-matching tap plugs on the relay were both placed in the 5.0-ampere position. For the first tests the through-current restraint tap plug was placed in the 25 per cent slope position and the burden on each current transformer, including leads and oscillograph shunts, was 1.0 ohm resistance.

Figure 9*A* shows a magnetizing-inrush test with the transformer being energized from the 13,800-volt side. No contact operation is indicated by vibrator number 6 although the crest of the first current peak measures 65 amperes and the pickup setting of the relay on sine wave current is 1.0 ampere rms.

Figure 9*B* shows a similar test in which the circuit breaker was closed near the

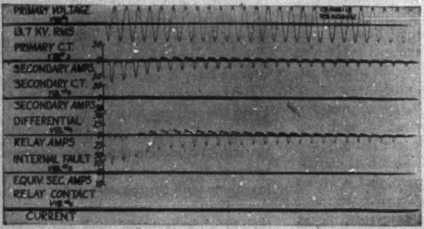

Figure 9. Oscillograms of performance tests of type HDD11A transformer percentage-differential relay with harmonic restraint

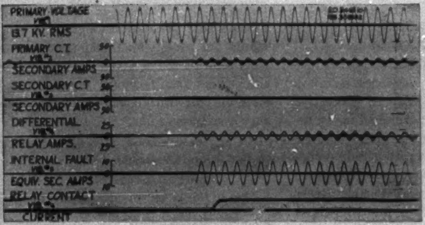
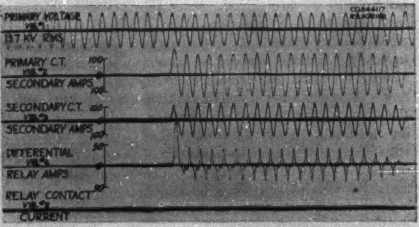
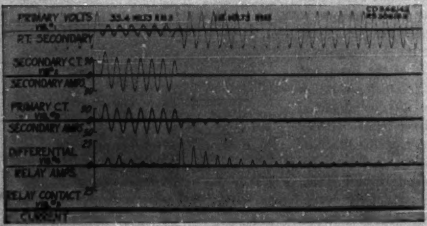
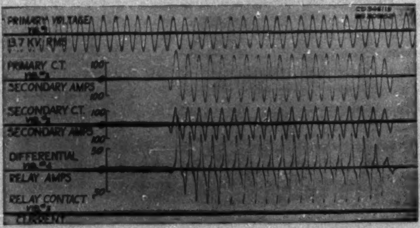
Oscillogram *D* (top right)—High-current through fault

Oscillogram *E* (bottom right)—High-current through fault with ten per cent ratio unbalance









crest of the voltage wave so that almost no inrush current was obtained. Six and one-half cycles after the transformer was energized a resistance load, simulating an internal fault, was connected across the 460-volt winding of the transformer, between the transformer and the 600/5-ampere current transformer. This load drew a current equivalent to 5.5 amperes rms in the current-transformer secondary circuit. Vibrator number 6 shows operation of the relay contacts in $1^1/_4$ cycles.

Figure 9*C* shows a test of the relay on the magnetizing-inrush current caused by the recovery of the transformer voltage following the clearing of a through fault. For this test, the transformer was supplied with power from the 460-volt side through another smaller transformer, the impedance of which simulated the impedance of a long transmission line. A short circuit was applied to the 13,800-volt side (now the secondary side) of the protected transformer, just outside of the 20/5-ampere current transformer. As shown by vibrator number 1, the primary voltage of the transformer as measured on the secondary side of a 460/115-volt potential transformer dropped from its open-circuit value of 112 volts to 33.4 volts when the fault was applied. Although the fault current was only seven times the rating of the current transformers and the total burden of each current transformer was only 0.5-ohm resistance, an appreciable differential current, probably due to residual magnetization in one of the current transformers, is shown by vibrator number 4 during the fault period. When the fault was cleared by operation of an oil circuit breaker on the 13,800-volt side, the transformer voltage returned to normal causing a magnetizing-inrush current to flow. Although lower in magnitude than the inrush current obtained when energizing an initially "dead" transformer, it is still high enough to cause the operation of relays not equipped to prevent it. The harmonic-restraint relay was restrained from operating in this test as is demonstrated by vibrator number 5.

Figure 9*D* shows a heavy through-fault test. The transformer was again supplied from the 13,800-volt side and a short circuit was applied to the 460-volt side just outside the 600/5-ampere current transformer. The current obtained was approximately 18 times the normal ratings of the current transformers, each of which had a total burden of 1.0 ohm resistance. For this test the through-current restraint tap plug was placed in the 15 per cent slope position, although the usual practice on other type percentage-differential relays is to use 25 per cent slope or more for transformer protection. Vibrator number 5 shows that the relay was restrained from operating although the 600/5-ampere current transformer broke down in ratio considerably more than did the 20/5-ampere one, resulting in a large differential current. The wave shape of the differential current, however, indicates the presence of a considerable third-harmonic component which made it possible for the harmonic-restraint feature of the relay to aid the through-current restraint in preventing false operation.

Figure 9*E* shows an even more severe test of the ability of the relay to restrain itself from operating on through faults. The differential system was unbalanced ten per cent by changing the transformer primary tap from the 13,800-volt position to the 12,420-volt position. In addition, this change resulted in an increase in the fault current to approximately 20 times the current transformer ratings. The already faltering 600/5-ampere current transformer was further embarrassed by increasing its burden to 1.5 ohms resistance while that of the 20/5-ampere current transformer was reduced to 0.5 ohm resistance. The resulting differential current is much greater, as would be expected, but owing to the harmonic restraint no relay operation resulted although only 15 per cent through-current restraint was used. It is obvious from the magnitude of the differential current that a higher percentage of through-current restraint would be required if it were used alone, without the aid of the harmonic restraint.

Application—Selection of Current Transformers

As with other high-speed protective relays, care should be exercised in the selection of current transformers for use with *HDD*-type relays to obtain types and ratings giving adequate performance during the transient period immediately following initiation of a fault. This is particularly important where the application is near the generators because of the slow decay rate of the d-c component in offset-wave fault currents obtained there. The time-constant for the d-c component increased with the size of the generator, reaching values of 0.25 to 0.35 second for the largest ones. The d-c component of the fault current will have this slow decay rate for a fault directly at the machine terminals. As the electrical distance to the fault increases the intervening transmission lines, cables, reactors, transformers, bus bars, etc., introduce resistance into the fault-current circuit at a more rapid rate than inductance so that the time-constant decreases rapidly at first, more slowly afterward, reaching values of 0.02 second or lower at the distribution points.

The d-c component requires much more flux in the current-transformer core for its faithful reproduction in the secondary circuit than does the a-c component, nearly 100 times as much for a fully offset 60-cycle wave having a 0.25-second d-c time constant. The cores of ordinary current transformers become saturated in attempting to carry this flux and ratio breakdown occurs. Under extreme conditions the breakdown may be almost complete. In the secondary differential circuit, then, the current transformer does not effectively distinguish between an internal and an external fault and no relay can be expected to give correct performance. While harmonic restraint, particularly when combined with through-current restraint, is an effective factor in promoting correct performance on values of current transformer saturation approaching this extreme, still it is not a "cure-all" and there is a limit beyond which a relay so equipped will fail. Current transformers should be selected to avoid this extreme saturation.

Standard current transformers, particularly the bushing types, are in general satisfactory for applications where the maximum fault current does not exceed 20 times the current-transformer rating and the d-c time constant does not exceed 0.05 second. Where the application is made to the protection of a transformer located near generation longer time constants are usually met and special consideration should be given the selection of the current transformers. Special large-sized current transformers may be necessary in extreme cases.

Medium-Capacity Air-Blast Circuit Breakers for Metal-Clad Switchgear

R. M. BENNETT
MEMBER AIEE

B. W. WYMAN
ASSOCIATE AIEE

Synopsis: The cross-blast principle of arc interruption has been shown to provide maximum air economy; consequently this method of interruption is well suited for use in an air-blast breaker that must conform to the rigid space requirements and small phase spacings encountered in medium-capacity metal-clad equipment.

It is shown that proper co-ordination of the operating mechanism, air supply, interrupting chamber, and resistor make possible a design to meet these requirements.

The principle of operation is discussed and it is shown how a resistance is utilized to provide further air economy.

THE trend in the design of modern switchgear has for some years been in the direction of increased compactness and reliability. A marked advance in this development was the advent of the oil-blast principle[1] of circuit interruption, by which a stream of oil was made to flow across the arc path in a confined arcing chamber in such a manner as to sweep the ionized gases from between the contacts. The use of the oil-blast principle made possible drastic size reductions and increased the available ratings for metal-clad switchgear. A complete line of low-oil-content short-interrupting-time oil circuit breakers utilizing this oil-blast principle, rated from 25,000- to 500,000-kva interrupting capacity, were developed for vertical-lift metal-clad switchgear.

Recent years have seen a strong demand for oilless circuit breakers resulting from growing appreciation of their superiority.

As recent papers[2,3,4] have pointed out, air circuit breakers possess certain inherent advantages over oil breakers, which can be obtained only by the complete elimination of oil as an interrupting medium. These advantages, which arise from the nature of air circuit breakers, include freedom from oil fire and explosion hazards, cleanliness, and ease of inspection, and perhaps most important of all, greatly lowered maintenance due to the fact that it is no longer necessary to drain and renew the interrupting medium. This is particularly advantageous in breakers where the interrupting medium also acts as the insulation medium and is deteriorated by the action of the arc.

These benefits arising from the use of air circuit breakers are complementary to the well-known advantages of metal-clad gear; consequently, it became highly desirable to develop a medium-capacity air circuit breaker for use in metal-clad switchgear.

In a paper presented at the 1940 AIEE winter convention,[3] by D. C. Prince, J. A. Henley, and W. K. Rankin it was shown that the European designs for medium voltages, using radial-type nozzles, require excessive amounts of air to meet the requirements of American practice and they described the application of the cross-blast principle to overcome this difficulty. At the same time H. E. Strang and A. C. Boisseau[4] showed how this principle is applied in the construction of the high-capacity breakers for 15-kv service.

These breakers which are of the cubicle type are available for service in ratings from 500,000 kva to the highest capacity required at 15 kv.

Oilless circuit breakers demanded for metal-clad installation are of 250,000- and 500,000-kva rating. In the development of these air-blast breakers, the cross-blast principle of circuit interruption, characterized by the economical use of compressed air, has made possible the design of an extremely compact unit.

Requirements

Obviously any air circuit breaker that is expected to compete with the well-accepted oil circuit breaker must not only offer new features that are desirable but must also have ratings comparable to and be in every way as reliable and

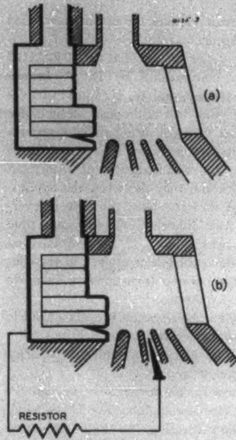

Figure 3. Interrupting chamber of air-blast circuit breaker

(*a*)—Without shunt resistor

(*b*)—With shunt resistor

efficient as its predecessor. To be acceptable for metal-clad service, this air-blast breaker must also be comparable in size to oil circuit breakers of the same rating. This means, for example, that a 250,000-kva circuit breaker must be accommodated by a 26-inch metal-clad structure with six-inch phase spacings for the circuit breaker bushings. Figure 1 shows the space available for the 250,000-kva air circuit breaker in the metal-clad compartment.

Inasmuch as nearly all switchgear manufacturers have standardized on the vertical-lift type of construction as the best possible arrangement and as providing maximum space for potheads and cable termination and for space conservation, it was highly desirable that an air-blast circuit breaker for metal-clad switchgear retain this feature. This type of construction requires the use of vertical bushings located at the top of the breaker.

One further well-recognized requirement of such a breaker is that all flame emission during interruption at full capacity must be eliminated.

Theory of Interruption

In order to meet the foregoing requirements, particularly with respect to size, a very careful co-ordination of the various parts of the breaker was necessary. Briefly, the breaker must consist of five parts, a control valve, a mechanism, an air tank, an interrupting chamber, and a space for disposing of the arc products. The compact arrangement of these parts in the completed breaker is shown by figure 2.

It has been recognized that the dimensions of the air tank, interrupting chamber, and muffling structure are all interrelated. This relationship will be briefly described.

Figure 3*a* shows the interrupting chamber of a typical cross-blast breaker. It is the purpose of this chamber to permit the arc, which is formed between the separating contacts, to be blown into a series of loops as in figure 4.

Except at the current zero the arc path is continuous but at the current zero no energy is available to further ionize gas, consequently the high-velocity air parts the arc stream at the foreward edge of the barriers and sweeps the remaining arc segments away into the exhaust structure.

As these arc segments are swept away by the air blast at the foreward edges of the barriers, they are replaced by fresh dielectric. The rate at which dielectric strength is inserted between the contacts depends upon the dielectric strength and velocity of the air stream, and the number of points at which fresh dielectric separates the arc stream. As the current reaches zero, however, the voltage across the breaker contacts begins to rise at a rate that is dependent upon the constants of the particular circuit being interrupted[5] and it is widely recognized that the rate at which this voltage appears across the breaker contacts is a measure of the severity of the interrupting duty imposed upon the breaker.[3]

For successful interruption, the dielectric strength inserted by the air stream between the terminals of the circuit breaker must increase at a rate greater than the rate of rise of recovery voltage. Thus if the air velocity is 0.01 inch per microsecond and the dielectric strength of air is 50,000 volts per inch, the rate of rise of dielectric strength of a single break is 50,000×0.01 or 500 volts per microsecond. That is, the rate of rise of dielectric strength between the breaker contacts is given by multiplying the dielectric strength of the air by the air velocity and by the number of breaks in the arc stream. At the pressure differences used, this velocity is very nearly constant at the velocity of sound. But the dielectric strength of this air is almost directly proportional to the pressure; consequently, the rate of rise of dielectric strength is proportional to the product of the air pressure and the number of breaks in the arc stream.

Consider now the air consumption of the device; with the velocity constant, the quantity of air discharged depends only upon the air pressure and the number and size of the air passages between the barriers. Consequently, the air consumption is directly proportional to the

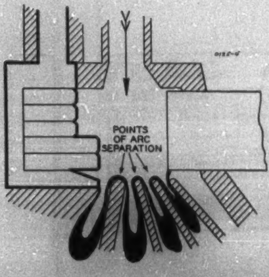

Figure 4. Interrupting chamber of air-blast circuit breaker showing configuration of arc

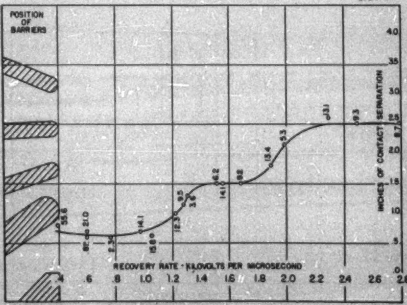

Figure 5. Contact separation of cross-blast air circuit breaker at interruption versus rate of rise of recovery voltage

Numbers indicate current interrupted in kiloamperes. Tests made at reduced air pressure rate of increase of dielectric strength required of the breaker. This rate of increase of dielectric strength must, of course, always exceed the rate of rise of voltage at the breaker terminals after a current zero which is purely a function of the circuit in which the breaker is employed. Therefore, it is evident that, with the number of air passages fixed by the rate of increase of dielectric strength required, the only way of achieving air economy is to reduce the size of each of the air passages through which the arc is blown to form a loop. (See figure 4.) However, it has been found that these openings are fixed by the amount of current to be interrupted. That is, they must be sufficiently great in area to permit the formation of a loop in the arc before current zero. If the openings are too small, the arc remains straight across the barriers up to the current zero. In this case the arc products cannot be forced out through the restrictions between the barriers before the recovery voltage rises and causes re-establishment of the arc.

The importance of the dimensions of these air passages is well illustrated by comparison of the curves in figures 5 and 6. Figure 5 shows that adequate air passage dimensions make the operation of the interrupting unit literally independent of current within its range, but dependent only upon the recovery rate of the circuit involved. Each point shown in figure 5 is the average of a large number of tests and represents the number of inches of contact separation required to interrupt the indicated rate of rise of recovery voltage under conditions of a single value of reduced tank pressure. The number associated with each point is the current interrupted in kiloamperes. Note that the points form a curve without any regard to the current magnitudes shown. It may be noted that a distinct flattening of the curve occurs at each barrier indicating that as each additional barrier is introduced into the arc path, permitting the formation of a new break in the arc stream, there occurs a definite increase in the rate of rise of recovery voltage that may be interrupted.

Figure 6 represents a series of tests in which the openings between the barriers were too small and were partially choked by the higher currents so that displacement of the arc products was delayed and additional breaks in the arc stream were required to produce interruption.

It has been indicated that the volume of air required and consequently the size of the air tank, is directly proportional to the rate of rise of recovery voltage.

Figure 8. Gas collected from one phase of 250,000-kva air-blast circuit breaker in rubber balloon fastened to exhaust tube

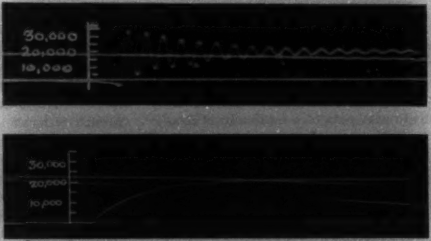

Figure 7. Cathode-ray oscillograms of recovery voltage after interruption

(*a*)—Without shunt resistor

(*b*)—With shunt resistor

In order to provide an adequate factor of safety for application on any circuit, the cross-blast breaker must have sufficient air passages and be supplied with sufficient air to interrupt the highest recovery rates encountered in practice. However, if the recovery rate of the circuit can be modified by a shunt impedance (3) and held at a known low value a smaller number of air passages are required and great air economy can be achieved. It is imperative to obtain maximum air economy in order that the air tank may be sufficiently small to fulfill the space requirements of the breaker.

To keep the air consumption of this breaker low then, the rate of rise of the recovery voltage has been limited by the use of a shunt resistor which reduces this rate to a maximum of 500 volts per microsecond regardless of normal circuit rates of rise.

Figure 3*b* shows the interrupting element and resistor connection employed.

With such an arrangement the recovery voltage appearing across the contacts after the circuit has been interrupted, breaks down the gap between the blade contact and the resistor electrode inserting the resistance between the contacts. The small current flowing through the resistance is interrupted after further movement of the blade contact which places a barrier between the resistance electrode and the moving contact. This

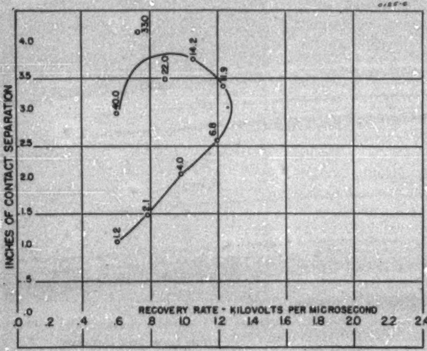

Figure 6. Contact separation of cross-blast air circuit breaker at interruption versus rate of rise of recovery voltage

Air passages between barriers too small

Numbers indicate current interrupted in kiloamperes. Tests made at reduced air pressure

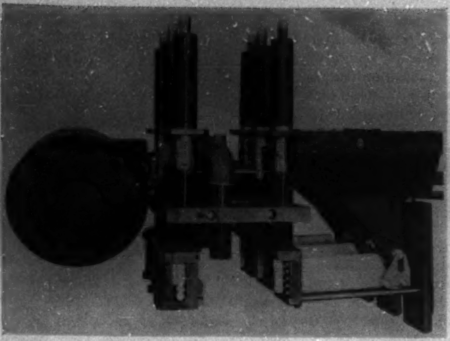

Figure 9 (left). Mechanism and contact arrangement of air-blast circuit breaker for metal-clad switchgear

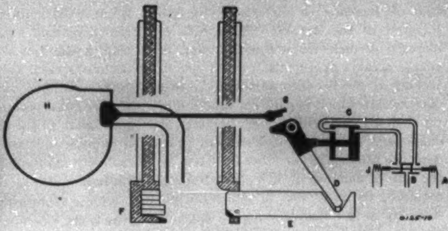

Figure 10. Schematic diagram of circuit-breaker mechanism

small resistor current is easily interrupted as it is nearly in phase with the applied voltage so that the rate of rise of the resistor circuit voltage is very low.

Figure 7 shows two cathode-ray oscillograms of the recovery voltage after interruption, both with and without a shunt resistor. In the first the rate of rise of recovery voltage is determined entirely by the external circuit constants and overshoots to a maximum of nearly twice the normal 60-cycle peak voltage. In the second, is shown an interruption of the same external circuit but with a shunt resistor added to the breaker. The rate of rise of recovery voltage in the latter case is reduced from 2,700 to less than 100 volts per microsecond and does not rise above its 60-cycle crest. This feature is of additional importance on circuits where switching transients are dangerous.

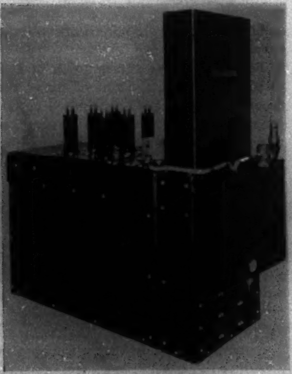

Figure 11. Complete metal-enclosed air-blast circuit breaker

In the process of interruption, considerable hot gas is produced and must be cooled and removed from the arc chute. This cooling is accomplished by two methods: by mixing the gas with cool air from the air blast and by driving it between closely spaced copper cooling plates which present a large surface to the air stream. After thorough cooling inside the arc chute, the gases are carried through exhaust tubes and delivered outside the metal-clad structure.

These cool gases have been collected in a rubber balloon fitted to the top of the exhaust tube for the purpose of gas analysis and a photograph of such a test (figure 8) at 36,000 amperes indicates the remarkably small amount of air and gas released from one phase during interruption.

Mechanism

The size of the mechanism of the air blast breaker is dependent largely upon the mass and speed required of the moving contact and the magnitude of the magnetic forces encountered in operation. The mechanism is pneumatically operated and its compactness and strength are well illustrated by the photograph of figure 9.

The mechanism consists of a two-way control valve that supplies air to two double-acting operating pistons connected directly to the operating shaft which in turn is directly connected to the blade-type contacts through operating arms of insulating material. The crankshaft also opens and closes the main air-blast valve at a predetermined position in the stroke of the blade contacts. This streamlined air-blast valve releases a blast of compressed air into a distributing manifold connected through insulating air tubes to the interrupting chamber of each of the arc chutes.

The action of the breaker can be seen from the schematic diagram in figure 10. With the breaker in the open position as shown, energizing closing coil *J* opens the control valve *B* to admit compressed air to the closing side of piston *C*. This operates the insulated arm *D* which moves the blade type contact *E* to engage the stationary finger contacts *F*. The moving blade makes contact first with the arc-resisting tungsten-silver arcing contacts. The opening of air-blast valve *H* by cam *G* shortly before the contacts meet allows a blast of compressed air to be directed between the contacts. The control valve is "sealed in" the closing position until the breaker is fully closed at which time it is released by a mechanically operated switch.

With the breaker in the closed position, energizing the closing coil *A* opens the control valve *B* to admit compressed air

to the opening side of piston *C*, thereby opening the blade contacts and the blast valve *H* to admit a blast of compressed air across the contacts effecting interruption.

It will be noted from the mechanism photograph and the schematic diagram that the blade motion is horizontal and at right angles to the vertical studs. The magnetic forces on the moving contact due to the flow of current are, therefore, downward at right angles to the motion of the blade contact. This arrangement makes the closing speed of the breaker independent of the short-circuit current and eliminates any possibility of stalling the mechanism during closing.

One of the advantages of the air-blast breaker is the relatively small contact erosion experienced.[4] This characteristic is the result of a number of factors. The high closing and opening speeds attainable mean that the arc duration is very short, but equally important is the use of an air blast during closing as well as opening. It is found that the increased dielectric strength of the compressed air prevents the formation of an arc until the contacts are very nearly closed and in addition the air blast directs the arc to the arcing fingers and provides excellent cooling. The combination of these features has reduced contact erosion in air-blast breakers to a negligible amount, providing considerable improvement over oil breakers.

When the breaker is in the open position, the blade contacts are entirely withdrawn from the arc chute and act as internal disconnectors providing a clear air break between the contacts.

Removal of the interphase barriers permits a full view of these contacts, their condition being a good indication of the condition of the stationary finger-type contacts as well. If the blade contacts show any appreciable erosion, the stationary finger contacts can be easily taken out for inspection without removing the arc chutes.

The circuit breaker is completely enclosed in metal as shown by the photograph in figure 11. Each phase of the breaker is isolated by interphase barriers of high dielectric strength. The whole circuit breaker is arranged to be as easily removable from the metal-clad cabinet as the familiar oil breaker, figure 12 being a photograph showing the breaker disconnected and partially removed. Figure 14 is a photograph of metal-clad switchgear incorporating air-

blast circuit breakers.

Table I is a set of three-phase interrupting tests made for the representatives of the American Gas and Electric Company. They have been pioneers in the application of the air-blast circuit breaker for metal-clad service and now have eight in operation.

Figure 13*a* shows the operation of the 250,000-kva air-blast breaker closing against a peak current of 96,000 amperes, 57,000 amperes rms, and interrupting 290,000 kva at 4,400 volts.

Table II is a set of three-phase tests showing the operation of the 250,000-kva air-blast breaker at 14,500 volts and figure 13*b* shows the interruption of 315,000 kva at 14,500 volts.

Conclusion

It should be pointed out that the adaptability and flexibility of the air-blast principle of circuit interruption which was used in developing the highest capacity circuit breakers for 15-kv service[4] has also been used as the solution of the problem of a 250,000- and 500,000-kva oilless circuit breaker for metal-clad service. The air-blast principle also shows promise of being readily applicable to high-voltage outdoor circuit breakers if sufficient interest should develop.

Synopsis: This paper describes the behavior of water as a dielectric, in particular with reference to its use in water circuit breakers.

Water is generally considered to have the properties of an electrical conductor rather than those of an insulator. There are, however, a few applications where the dielectric rather than the conductive properties of water are of importance, as, for example, in its use as the interrupting liquid in circuit breakers. Here the water between electrodes must withstand full circuit voltage during the closing operation until the electrodes are in metallic contact, and also in the opening operation following extinction of the arc, until some auxiliary switch in series can open.

Since there appears to be very little published information available on the subject, further knowledge of the behavior of water as a dielectric seemed to be of considerable interest and importance. To secure this information, a study of the subject was undertaken, the results of which will be reported in this paper.

Experimental data are presented which indicate that electric breakdown between electrodes immersed in water is, in general, determined by the temperature rise produced by the leakage current in the water. Breakdown appears to occur when steam generation begins. Calculation of time to cause temperature rises to 100 degrees centigrade in the water agree closely with observed time between applied voltage and breakdown.

When surge voltages of such short duration as to cause negligible heating are applied to electrodes submerged in water, the dielectric strength of water is found to be of the same order of magnitude as for insulating oils.

In comparing the properties of insulating liquids commonly used as dielectrics, with water, the most outstanding difference is the very much greater conductivity of water. The following table shows a comparison of the approximate conductivities of water and commonly used circuit breaker oils:

	Ohms Per Centimeter Cube	Conductivity Compared to Oil
Insulating oil	10^{16}	1
Good distilled water	5×10^{6}	2 billion
Tap water	5×10^{4}	200 billion

From the above table it is evident that, with equal electric gradients, water will absorb from 2 billion to 200 billion times as much heat energy due to current leakage through the liquid dielectric, as insulating oil. Since this thermal effect is of an entirely different order of magnitude in the water, it might be expected to play an important part in breakdown of water, whereas in oil or other highly insulating liquids, its effect would be negligible. Our investigations clearly demonstrate that this thermal effect is the determining factor in breakdown where sustained voltages are applied, both with high-resistivity distilled water and with comparatively low-resistivity tap water.

Testing Procedure and Apparatus

Since the comparatively low resistivity of even distilled water results in an appreciable current flow between submerged electrodes during a dielectric test, standard dielectric test transformers of small capacity cannot be used because of excessive regulation. The large 27,000-kva testing transformers of our Trafford laboratory were, therefore, used as a voltage source.

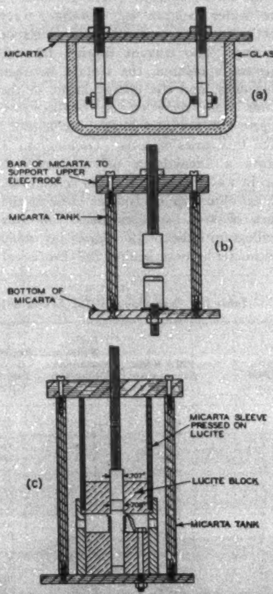

Figure 1. Apparatus used for dielectric tests on water

In making the tests, water of known resistivity was placed in a container which also held a pair of adjustable electrodes. Figure 1 shows three such vessels. The electrodes used were 1.5-inch sphere gaps, $^3/_4$-inch rod gaps with an edge radius of $^3/_{64}$ inch, and rod gaps 0.707 inch diameter, with very slight edge radius. The rod gaps on which the majority of tests were made were faced with copper "elkonite" to prevent burning by the current flow following breakdown.

Since the presence of a thermal effect would be evidenced by a delayed breakdown, a cathode-ray oscilloscope was connected in parallel with the gap being tested, so that the number of half cycles of applied voltage on the gap before breakdown occurred could be visually observed on the cathode-ray-tube screen. For the longer times a calibrated backup breaker was used to estimate the time of applied voltage. Magnetic oscillograms were also taken in many of the tests where sufficient accuracy could not be obtained by the above methods.

Breakdown in Water With 1.5-Inch-Diameter Sphere Gaps

In this series of tests, 1.5-inch sphere gaps were mounted in a horizontal plane in the glass bowl container, and submerged in distilled water with a resistivity of 125,000 ohms per centimeter cube. The gap length was varied, voltage being kept constant at 14,000 rms volts. It was found that with gap lengths in excess of 0.375 inch, breakdown did not occur for well over 20 half cycles (60-cycle circuit) after voltage was impressed. As the gap length was further shortened, the time delay between application of voltage and breakdown continued to decrease, in a manner as shown in table I. These results are shown graphically in the curves of figure 2. The last two tests in table I give re-

* Formula used in computing is $H=\frac{2E^2\cdot n}{504\rho l^2}$ calories per cubic centimeter; E = rms volts, n = half cycles, ρ = initial resistivity, ohms per centimeter cube, l = gap length, centimeters.

sults for the condition of voltage reduced from 14,000 to 4,600 volts. It may be noted here that there is a similar time lag to breakdown except that the time is now much longer than at the higher voltage.

Table II shows similar data (also shown graphically in figure 3) but for comparatively low-resistivity water. In this series of tests there was some drop in voltage in the current limiting reactor, and hence the column of voltage across the gap has been computed from the known constants of the circuit. In addition to the constant voltage condition, a series of tests was also made keeping gap length constant at 0.25 inch, and varying the impressed voltage.

Breakdown Between 0.75-Inch-Diameter Rod Gaps With $^{3}/_{64}$-Inch Edge Radius

These tests were similar in nature to those described above for the sphere gaps. The container, however, was of Micarta (shown in figure 1) and the electrodes were in a vertical plane.

Since it was observed in the first series of tests that the resistivity of water is extremely sensitive to temperature changes, careful observations of water temperatures and water resistivities were taken throughout the tests.

Data for the rod-gap tests using distilled water are presented in table III, and similar data for low resistivity water are given in table IV. Graphical results from these data are shown in figures 4 and 5.

Breakdown of Water With a Uniform Potential Gradient

In the tests described above, the field between the electrodes is evidently not absolutely uniform. For the sphere gap at $^{3}/_{8}$-inch separation, the maximum gradient is approximately 13 per cent higher than the minimum gradient. The nonuniformity increases with increasing gap length. Hence, especially for the longer gaps, there is some error in assuming a uniform gradient along the shortest filament of water between electrodes.

In order to observe breakdown in water with practically uniform potential gradient, another test cup was constructed as shown in figure 1*c*. In this cup electrodes having a diameter of 0.707 inch were placed in a Lucite cylinder of 0.709 inch internal bore, the test cup being so arranged that current can flow only through the water between the electrodes in the Lucite cylinder. The gradient on the water column is, therefore, very nearly uniform, regardless of electrode spacing. The current flowing through this water column, the voltage between electrodes, and the energy input to the water were recorded on oscillograms. Figure 8 shows three typical oscillograms from this series of tests. Oscillogram *A* shows a breakdown on a 0.125-inch gap in water at 19.8 degrees centigrade, 90,000 ohms per centimeter cube at the start of test. Measurements on this oscillogram indicate 79 calories per cubic centimeter input as against the theoretical value of 80.2. Oscillogram *B* shows a breakdown on a 0.5-inch gap in water of initial temperature of 17.5 degrees centigrade and 96,000 ohms per centimeter cube initial resistivity. The wattmeter record shows a total input at breakdown of 119 calories per cubic centimeter as against the theoretical 82.5 calories to start boiling. The oscillogram shows, however, that the current actually began to decrease after an input of 96 calories per cubic centimeter. This appears to indicate that minute bubbles of steam formed throughout the water volume, having the effect of decreasing the cross-sectional area of the water column. Pressure was undoubtedly also built up within the electrode volume since the lower contact was held in place by a spring pressure

* Formula used

$$H = (10.5 + T_i)\left(\epsilon^{\frac{0.00307 E^2 V n}{504 \rho l^2}} - 1\right) \text{ calories per cubic centimeter}$$

V = viscosity in millipoises
E = rms volts
n = half cycles
l = gap length in centimeters
ρ = ohms per centimeter cube

of approximately nine pounds per square inch. The additional heat input can, therefore, at least partially be accounted for by the increased boiling temperature due to pressure substantially higher than atmospheric.

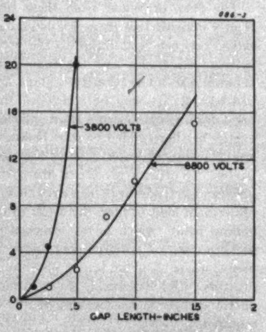

Figure 3. Time delay in breakdown of tap water between 1.5-inch spherical electrodes

Initial water resistivity about 4,700 ohms per centimeter cube. Applied voltages 3,800 and 8,800 rms volts

The current decrease seen in figure 8*B* is typical of long gaps, whereas immediate breakdown at the first appearance of gas seems to occur on short gaps as indicated on oscillogram *A*.

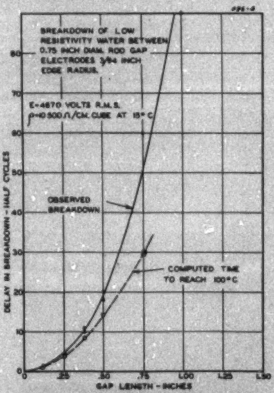

Figure 4. Comparison of observed and computed data for time delay in breakdown of low-resistivity water

On very short gaps with high applied gradients, breakdown occasionally occurs before boiling begins. Oscillogram *C* illustrates this case. Here 7,500 rms volts were applied to a 1/16-inch gap, the initial water conditions being 19.5 degrees centigrade, 115,000 ohms per centimeter cube. The oscillogram indicates that breakdown occurred near the first voltage peak after an input of 65 calories per cubic centimeter. Another test on a 1/16-inch gap broke down after an input of 41.5 calories per cubic centimeter. One-eighth-inch-long gaps with 13.8 kv applied also occasionally broke down before sufficient energy to cause boiling had been absorbed. In these cases, breakdown in water appears to be similar to breakdown in oil.

Breakdown of Gaps Having Air and Water in Series

In tests on water breakers, breakdown through the water has been observed on some occasions, during the closing operation, often resulting in considerable explosive effects. Such breakdowns appear to occur when the moving contact is close to, but not yet submerged below the water surface. A probable explanation of this behavior is, that as the contact approaches the water surface, the high dielectric constant and conductivity of the water compared to the similar quantities for the series air gap results in practically the full circuit voltage being applied across the air gap. The over-

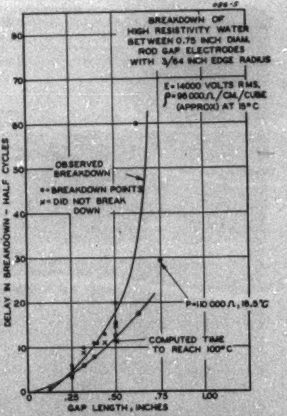

Figure 5. Comparison of observed and computed data for time of delay in breakdown of high-resistivity water

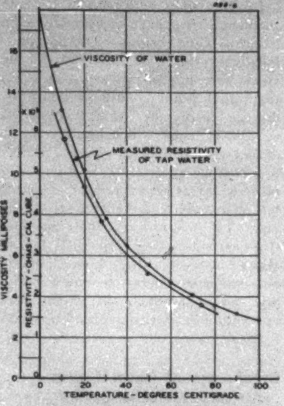

Figure 6. Comparison of resistivity versus temperature and of viscosity versus temperature curves for water

stressed air breaks down and arcs to the water, whence the current is conducted to the submerged electrode. However, after the air is ionized its effective dielectric constant approaches infinity, and hence there is an electrostatic force tending to draw the arc into the liquid. This action quickly forces the liquid out of the path between electrodes, completing the breakdown. For this reason it is evident that breakdown is particularly likely in closing operations as the contact approaches the water surface, or in opening operations after the contact has been drawn out of the water.

To study breakdown of gaps having air and water in series the tests recorded in table V were made. In this table, tests *BO* and *BN* show results with a 1.5-inch total gap. Test *BN* with both electrodes submerged broke down in two half cycles, whereas *BO* with a $^1/_{16}$-inch series air gap took three half cycles. While this seems contrary to the above theory, it should be remembered that a finite time is required to draw the arc down through the water to the submerged electrode, and it is quite possible that for conditions where the submerged gap breakdown is already very short, breakdown time with series air and water gaps may be, as indicated in these tests, as long as with water alone.

That this is not generally the case, however, is shown by tests *BW*, *BX*, and *CC*, where the breakdown time with series air gaps is seen to be less than half as long as with submerged electrodes. These tests, as well as tests *BQ*, *BP*, *BR*, and *BU* show, furthermore, that the time interval between application of voltage and breakdown with an air gap in series is independent of the air gap length. When, however, the air gap is increased to such length that it alone can withstand the full circuit voltage, breakdown does not occur at all. This condition is indicated in test *BU*.

In test *BY*, a wire screen was placed on the water surface to prevent the ionized path from being drawn down through the water. Breakdown rose to seven half cycles, comparable with the submerged electrodes. *BZ* is a similar test, but in this case a brass plate with a central hole was placed at the water surface. A wire was connected to this brass plate and brought to within 0.1 inch of the electrode above water, so that initial breakdown would occur to the wire rather than to the water surface. Here also the breakdown time was seven half cycles, comparable to the time with submerged electrodes.

Discussion of Results

The data presented from these tests clearly indicate that there is a definite relation between heat input to the water between electrodes and the time delay between the application of voltage and breakdown. It may be concluded that breakdown usually occurs when sufficient energy has been added to start boiling in any filament of water joining the electrodes. In order to produce a steam path between electrodes it is necessary to supply enough heat to raise the water to the boiling point, which is, at atmospheric pressure $(100-T_i)$ calories per cubic centimeter, where T_i is the initial water temperature. For pressures above atmospheric slightly higher heat input will be required.

The heat input per cubic centimeter to a filament of water between parallel electrodes is

$$\frac{E^2t}{4.2\rho l^2} \text{ calories}$$

where E = volts, t = seconds, ρ = ohms per centimeter cube; l = gap length in centimeters. Expressing t as $n/120$ where n is the number of half cycles of 60-cycle applied voltage before breakdown occurs,

$$\text{Heat input per cubic centimeter} = \frac{E^2n}{504\rho l^2}$$

The condition under which this heat input causes boiling to begin is

$$\frac{E^2n}{504\rho l^2} = 100 - T_i$$

Solving for n,

$$n = \frac{(100 - T_i)(504\ \rho l^2)}{E^2}$$

This is the number of half cycles that the water should withstand voltage if breakdown occurs when steam begins to form. On the other hand, the experimentally determined value of n, the number of half cycles delay to breakdown, may be substituted in the formula to determine whether temperature rise thus obtained equals $100 - T_i$.

Checks of this kind have been made for the data with spherical electrodes of table I. The results are presented in column 6 of that table. It should be noted here that $\frac{\rho}{2}$ has been used in these computations as the average water resistivity. This is half of the initial value, which is a reasonable average between the values at the initial temperature and the boiling point.

These calculations show that for practically all tests the input to cause boiling is of the same order of magnitude as the computed energy input per cubic centimeter to the water between electrodes.

It was observed that the resistivity of water falls very rapidly with increase in temperature, the resistivity-temperature curve being approximately a displaced rectangular hyperbola. On comparing this curve with the viscosity-temperature curve for water (figure 6) it may be seen that the two are practically identical in shape. This similarity indicates that change in water resistivity with temperature results from a change of mobility of the ions as the viscosity varies, the total number of ions remaining practically constant. This relation affords a simple method of determining change of resistivity with temperature since the resistivity is proportional to the viscosity, a quantity for which accurate tables are available.

In deriving a more accurate expression for relating the variables of the heat input equation given above, it is convenient to make use of the conductivity-temperature curve for water. As shown in figure 7, this curve proves to be almost linear and may thus be expressed $C = A + BT$. We may now substitute $A + BT$ for $1/\rho$ in the heat input equation, thus taking into account the variation of resistivity with temperature. From the previously derived equation, calories per cubic centimeter input for a temperature change, dt, is

$$dT = \frac{E^2dt}{\rho l^2\,4.2} = \frac{E^2}{4.2l^2}(A + BT)\,dt$$

whence

$$\frac{dT}{A + BT} = \frac{E^2}{4.2l^2}\,dt$$

This equation can readily be solved, whence T may be expressed as a function of t. When this is done the calories input per cubic centimeter is found to be

$$H = \left(\frac{A}{B} + T_i\right)(\epsilon^{Kt} - 1) \text{ calories per cubic centimeter}$$

where

A = zero degree intercept of conductivity-temperature curve
B = slope of conductivity-temperature curve
$K = \frac{(BE^2)}{4.2l^2}$
T_i = temperature at $t = 0$
t = seconds
E = rms volts
l = gap length—centimeters

The above equation, substituting approximate constants, may be reduced to the following form:

$$H = (10.5 + T_i)\left(\epsilon\frac{0.00307E^2Vn}{504\rho l^2} - 1\right)$$

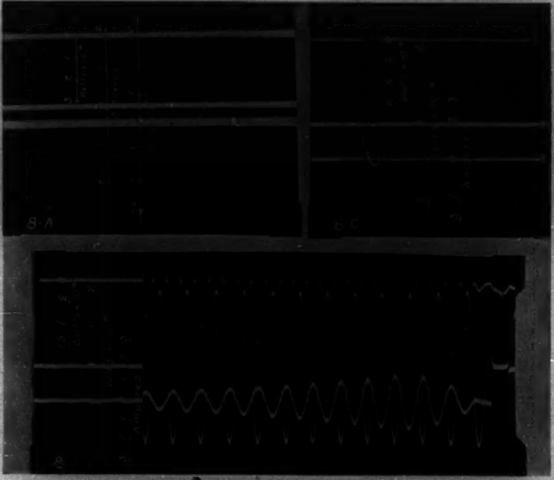

Figure 8 (right). Oscillograms showing breakdown in water with uniform potential gradients between electrodes

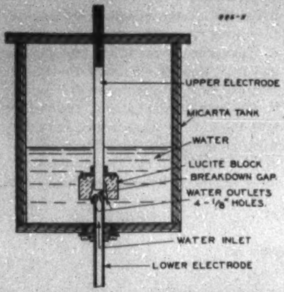

Figure 9. Apparatus used in studies of breakdown in rapidly flowing water

where

V = initial viscosity in millipoises (see figure 6)
ρ = initial ohms per centimeter cube
n = half cycles (60-cycle circuit)
ϵ = Naperian log base

Solving for n,

$$n=\left(\log_\epsilon\frac{110.5}{10.5+T_i}\right)\left(\frac{504l^2\rho}{0.00307E^2V}\right)$$

Using this equation, the number of half cycles that a given gap in water can withstand applied voltage before breakdown occurs may be calculated. These calculations should apply most accurately for those tests in which potential gradient was maintained constant.

Checking calculated and observed values for the test on a 0.125 inch gap corresponding to oscillogram figure 8*A* gives calculated time to breakdown 1.31 half cycles; observed from oscillogram, 1.30 half cycles. Checking again for the test on a 0.5-inch gap shown on oscillogram figure 8*B* gives calculated time to start boiling = 17.4 half cycles; observed from oscillogram = 19 half cycles. However, if for *H* the value 96 calories as actually measured on the oscillogram, is used instead of 82.5, the theoretical value, then the calculated time is 18.9 half cycles as compared to the observed value of 19 halves. In this case it should be noted that while boiling appears to have begun at 19 half cycles, breakdown did not actually occur until 25 half cycles had elapsed.

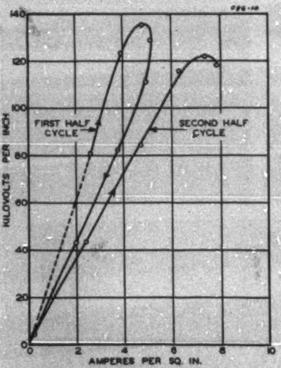

Figure 10. Volt-ampere curve for test shown in oscillogram A of figure 8

Gap length 0.125 inch

Further comparison of observed and calculated values of time to breakdown with a uniform potential gradient are given in table VI. In this table are given also the calories per cubic centimeter at breakdown as observed from the oscillographic records. These agree well with $(100-T_i)$, the theoretical value required for boiling at atmospheric pressure. If pressure rises above atmospheric as it probably did in tests that took several half cycles to reach the boiling point, a heat input in excess of $(100-T_i)$ per cubic centimeter is required.

It thus appears that close agreement between calculated and observed values of time to reach the boiling point can be attained where the potential gradient in the water is uniform, and that this also agrees well with the time of breakdown. For gaps in which the gradient is only approximately constant, it is found that the time to breakdown may still be estimated by calculation using the formula given above. The agreement of such calculations with observed times of breakdown may be seen from the tabulation of observed and computed values of two sets of data for 0.75 inch rod gaps as recorded in tables III and IV and shown graphically in curves of figures 4 and 5.

Figure 10 shows a volt-ampere curve plotted from the oscillogram shown in figure 8*A*. It may be observed that there is a steady decrease in resistance. The change in resistance appears to be a function of temperature, and at least approximately independent of the gradient on the water.

Breakdown in Water With Rapid Flow Across the Gap

Since breakdown in water appears to occur following a sufficient heat input to cause vaporization, it seemed probable that the electric breakdown of a gap could be prevented if a sufficiently high

velocity of water flow were maintained across the gap so that the water fails to reach the boiling point during the time it remains between electrodes.

To verify this conclusion, an apparatus as shown in figure 9 was constructed to cause rapid flow of water between the faces of a pair of electrodes. The gap used consisted of one-inch-diameter rods with $^3/_{64}$-inch edge radius. The one electrode through which the water emerged had a $^3/_8$-inch central hole.

This device was first tested under conditions similar to those which had held voltage for six or seven half cycles with stationary water between the electrodes, except that sufficient flow was provided that the gap should now, according to calculations, hold voltage indefinitely. However, breakdown occurred almost immediately upon application of voltage. A consideration of the flow conditions present in the arrangement showed that this was to be expected. The outward radial flow of liquid in the gap resulted in a maximum velocity of liquid at the center of the gap with deceleration toward the outer edge. Since the pressure at the outside was atmospheric, the pressure near the center must have been less than atmospheric. The fact that breakdown occurred immediately indicates that a very low pressure, probably lower than the vapor pressure of water, actually existed near the center of the gap.

These results thus serve to further confirm the theory that breakdown occurs at the boiling point of the water between electrodes. It also further emphasizes the fact that in flow devices great care in design must be used to prevent flow conditions such that reduced liquid pressures result at points of dielectric stress. This is true for oil devices as well as for water, although in the case of oil the chief factor causing decrease in dielectric strength with reduced pressures, results not from vaporization of the oil itself, but from release of gases dissolved in the oil.

In order to eliminate the low-pressure conditions which had caused breakdown in this gap, the electrodes were enclosed in a block of Lucite containing a small cavity surrounding the gap. The discharge path for the water from this cavity consisted of four one-eighth-inch holes, the area of which was considerably smaller than the minimum restriction at other points in the path of flow. Thus the pressure at all points between electrodes was maintained higher than atmospheric.

Under these conditions it was possible to hold indefinitely 9,340 volts on a 50-mil gap with a flow of 0.463 cubic inch per half cycle. This flow was sufficient to change the water between electrodes in 0.084 half cycle or to change all the water in the enclosing cavity in 0.8 half cycle. The computed time to reach 100 degrees for this condition with stationary water is about 0.6 half cycle. In another test we succeeded in holding 14 kv indefinitely on a 0.125-inch gap with a flow of 0.424 cubic inches per half cycle. This flow would change the water between electrodes once every 0.23 half cycle and would change the water in the cavity surrounding electrodes once every 1.0 half cycle. The computed time to reach 100 degrees in stationary water is about 1.5 half cycles.

It may thus be seen that breakdown can be prevented by sufficient flow of water past the electrodes. In these tests a flow somewhat greater than might be expected from calculations was required to prevent breakdown. It should be remembered, however, that even after the water has been moved out of the gap it is still being subjected to a considerable dielectric stress, and energy continues to be absorbed until it is discharged from the cavity around the gap. It is also probable that a percentage of the original water in the cavity still remains therein after a quantity of water equal to the volume of the cavity has been discharged from it. The fact that the flow required to prevent breakdown is of the right order of magnitude to evacuate the gap and surrounding cavity before boiling can begin is, therefore, another confirmation of the theory that breakdown occurs when the water reaches the boiling point.

Surge Tests on Water

In order to observe the voltage required to cause rupture of distilled water having a resistivity in the order of 50,000 ohms per cubic centimeter, a few tests were made using impressed surge voltages of such short duration that the heating of the water between electrodes was negligible. Under these conditions the following results were obtained:

Gap Length (Inches)	Surge Breakdown for Water (Kilovolts)	Surge Breakdown—Insulating Oil (Kilovolts)
0.1	58.5	
0.050	42.9	60.0
0.025	34.4	48.7

These tests indicate that water has approximately 70 per cent as great dielectric strength as oil on surge voltages.

Conclusions

1. Dielectric tests on water indicate that breakdown is generally due to thermal effects and does not occur until a filament of water between electrodes has been almost completely vaporized.

2. An exception to this rule occurs when gradients on the water exceed approximately 125,000 rms volts per inch. Breakdown then appears to occur before boiling, although generally not until considerable heat has been absorbed.

3. An equation has been derived for calculating the time for the water in a given gap to reach the boiling point. This time is found also to be approximately the time of breakdown of the gap.

4. Long gaps withstand voltage somewhat longer than the computed time to reach the boiling point. This is due in part to the loss of heat to contacts and surrounding water, and in part to formation of minute bubbles in the interelectrode space which tend to reduce the rate of heat input.

5. Gaps with air and water in series may, under certain conditions, break down faster than the same gap completely submerged in water.

6. Short gaps in water can withstand voltages far in excess of those resulting in breakdown on stationary water if the liquid between electrodes is rapidly renewed by flow between the contact faces.

Superposition Methods for Calculating Effects of Additions to Power Systems

V. G. RETTIG
ASSOCIATE AIEE

Synopsis: Outline of a group of methods that will permit calculation of all the common changes on power-system networks by superposition methods having as a basis the representation of loads as fixed currents. Investigation of the errors involved, and comparison with results obtained by assuming constant-impedance loads, when applied to the average power-system networks in operation today.

On a growing power system it frequently becomes necessary to calculate the effect of the addition of certain loads or lines to the existing system. With the present status of power systems, the calculation of additions is a much more common problem than the calculation of complete new networks. These calculations usually consist of determining the load division in old and new circuits and the voltage at certain principal supply points or substation busses. More specifically, loads in amperes are usually more important than the kilowatt and reactive kilovolt-ampere values. The need for this information has long been recognized and is evidenced today by the increasing attention which is being given to a-c boards.

The calculation of currents and voltages in networks has received a great deal of study in years past and hence the known mathematical methods of approach are quite varied. Among the better known ones are the direct application of Kirchoff's laws or of Maxwell's equations of cyclical currents, which lead to a solution of a number of simultaneous equations, or the use of the familiar impedance network transformations, such as the delta-star, star-mesh and the like, which permit simplification of complex networks until they can be handled by more direct methods. Other less known methods are based on the principal of superposition, on Thevenin's theorem, and on trial and error methods which depend largely on experience and ingenuity in handling for a reasonably direct solution.

Practically all of the direct methods that are commonly used are based on the representation of all lines and loads as fixed impedances and the networks are considered as complete new networks in which nothing is known of the current division in the various lines resulting from any existing loads. A solution by these methods involves all line and load impedances for each alternative set of connections under consideration. In a-c networks, where it is necessary to deal almost entirely with complex quantities, the solution of networks made up of even a moderate number of loads and lines becomes a long and tedious process. Moreover, the work required to solve a network increases in a much greater proportion than the increase in the number of impedances involved. For this reason, any method which would permit the elimination of some of the impedances from consideration would greatly simplify any solution.

It is the purpose of this paper to describe a set of simplified methods which can be used to calculate the effects of any of the changes or additions that are commonly made on a power network, to show where they can be applied to better advantage than any other method, and to show the limits of accuracy that can be expected for the common types of loads and lines.

Basis for Methods

It is assumed first, that all load currents on a system remain fixed in magnitude and in phase angle with respect to the voltage at one point on the system regardless of what changes are made in connections and in voltages at the various loads. For many very common types of lines and loads, this assumption simulates actual conditions much more closely than the usual representation of loads as fixed impedances. Since the load currents remain fixed during a given change, they need not be dealt with in calculating the effects of that change and the problem is thereby simplified to a great extent. The methods are actually a solution for changes in currents and voltages in parts of a network of lines which can be added to the originals to give corrected values and can in general be classed as superposition methods. Thevenin's theorem is the basis for some of the methods.

To compare the assumption of fixed load current as against fixed load impedance and determine how closely each of them represent actual conditions, it is necessary to examine the various types of loads that are commonly supplied by transmission and subtransmission lines of the average power system. In so far as the effects of voltage changes on loads are concerned, the loads can be divided roughly into three principal groups.

1. Loads for which the value of kilovolt-amperes is constant regardless of supply voltage change, and for which, therefore, an increase in supply voltage will cause a proportionate decrease in current. Examples of this type load are loads supplied through automatic voltage regulators and synchronous motor loads on which the fields are controlled to maintain constant power factor.

2. Loads for which the power component is constant regardless of voltage change and for which the reactive kilovolt-amperes increases with an increase in voltage. This is true in general of motor loads and series type street-lighting circuits supplied through constant-current transformers.

3. Loads for which an increase in voltage produces an increase in current. This is true of lighting load, resistance-type heaters, and similar loads.

Table I

	Group 1	Group 2	Group 3	Assume Fixed Impedance	Assume Fixed Current
Kilowatts	Constant	Constant	$KE^{1.6}$ to KE^2	KE^2	KE
Reactive kilovolt-amperes	Constant	KE to KE^3	KE^2	KE^2	KE

On power systems in general the amount of load in either of the first two groups is considerably larger than in the third group, this being particularly true of the Cincinnati system. Table I gives the relationships of kilowatts and reactive kilovolt-amperes to voltage in all of the above groups, as well as for the theoretical cases in which fixed impedance as well as

---

Paper 40-133, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted July 13, 1939; made available for preprinting July 16, 1940.

V. G. Rettig is in the electric distribution department of the Cincinnati Gas and Electric Company, Cincinnati, Ohio.

fixed current loads are assumed for calculating purposes.

Since the first two groups are the predominant groups, it becomes apparent that assuming the loads to draw fixed currents will give results which are at least as accurate and in most cases much more accurate than when the loads are assumed to be fixed impedances. Since the changes in voltage that are obtained by any one program of additions rarely exceed five per cent, the changes in load currents will rarely exceed that value. The change of power factor of the load in group 2 with change of load voltage tends to correct for the shift in phase angle of the load voltages on networks where the impedance angle of the lines is greater than the impedance angle of the loads. This condition exists on practically all power-system networks. The board-type ammeters and voltmeters from which the original readings are taken do not have a reliable accuracy of better than one per cent and in many cases not better than two per cent.

Description of Methods

Having indicated that the accuracy of the original assumptions is within accepted limits, it remains now to show the methods themselves and just how they simplify the calculation of additions to networks. There are four types of additions or changes to a system that are commonly made:

Case 1. The addition of a new load or the removal of an existing one from the system.

Case 2. The addition of a new circuit paralleling or partially paralleling existing circuits.

Case 3. A change in the impedance of a part of one of the existing circuits, such as might be made by changing conductor size.

Case 4. Changing of transformer or tap changer tap settings.

On an adequately metered system, it is possible to obtain the kilowatts and reactive kilovolt-amperes on the various circuits as well as for the principal loads, and the voltages on the principal busses for any existing setup. From these values, a comparatively small number of calculations will give the power and reactive components of currents as well as the voltage drops on various circuits expressed in terms of complex quantities. From these values all currents and voltages can be readily calculated with respect to one reference, for which the main supply bus voltage is usually chosen. Beginning, then, with this known set of conditions, changes in system connections will cause changes in the currents carried by the different lines. These changes in currents can be calculated for any of the above-mentioned four changes without considering the existing loads in any way. Direct additions of currents then give the new set of results.

For the purpose of illustrating the methods a simple form of transmission system is assumed in which the phase angles of all line and load impedances are assumed to be equal so that it will not be necessary to deal with complex quantities. The original values have no subscripts, the corrections are indicated by prime (′) and the corrected values by double prime (″).

Case 1. Addition of a Load

Figure 1 shows a single load of 210 amperes at C supplied by two parallel transmission circuits of nine ohms each, which, of course, divide the load equally and a new load of 126 amperes, which is to be added at A where the original voltage drop is 315 volts. The effect of load A can be calculated independently of the load at C and then the voltage drops and currents caused by the two loads added.

The load divides in the various circuits between bus E and point A inversely as the impedances of the paths regardless of the presence of other loads being supplied by the system. The impedance of A is:

$Z_a'' = \frac{3\times 15}{18} = 2.5$ ohms and the changes in currents and voltages become:

$E_{ea}' = Z_a'' I_n = 2.5\times 126 = 315$ volts additional drop

$I_{ea}' = \frac{E_{ea}'}{Z_{ea}} = \frac{315}{3} = 105$ amperes additional

$I_{eca}' = \frac{E_{ea}'}{Z_{eca}} = \frac{315}{15} = 21$ amperes additional

$E_{ec}' = Z_{ec} I_{eca}' = 9\times 21 = 189$ volts additional drop

$E_{ca}' = Z_{ca} I_{ca}' = 6\times 21 = 126$ volts additional drop

Corrected values of current and voltage are:

$$I_{ea}'' = I_{ea}' + I_{ea} = 105 + 105 = 210 \text{ amperes}$$
$$E_{ea}'' = E_{ea}' + E_{ea} = 315 + 315 = 630 \text{ volts}$$
$$I_{ac}'' = I_{ac} + I_{ac}' = 105 - 21 = 84 \text{ amperes}$$
$$E_{ec}'' = E_{ec} + E_{ec}' = 945 + 189 = 1{,}134 \text{ volts}$$
$$I_{ed}'' = I_{ed} + I_{ed}' = 105 + 21 = 126 \text{ amperes}$$
$$E_{ed}'' = I_{ed}'' Z_{ed} = 126\times 6 = 756 \text{ volts}$$

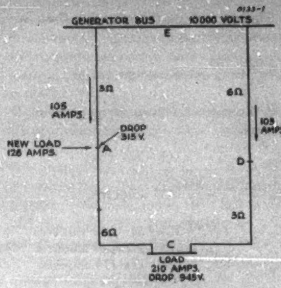

Figure 1. Addition of a new load

Case 2. Addition of a New Parallel Circuit

Figure 2 shows the original system with corrected currents and voltage drops resulting from the addition of the load at point A. The currents and voltages are such that Kirchoff's laws are again completely satisfied. A new circuit (Z_n) of three ohms is to be added from bus E to point D where the voltage drop is 756 volts. Therefore, with the new circuit connected to bus E and open at D the voltage between the new and old circuits at D will be 756 volts. When the lines are tied together at D, this voltage will cause current to flow in the new circuit and additional currents in the existing circuits until Kirchoff's laws are again satisfied.

The loop on which this voltage acts is made up of the new line connected in series with all other paths, which are in parallel between point D and bus E. The two other paths between point D and bus E are the 6-ohm line DE and the 12-ohm line $DCAE$, which when connected in parallel give

$$Z_{ed}\ (\text{total}) = \frac{12\times 6}{12+6} = 4 \text{ ohms}$$

and the impedance of the total loop, made up of this impedance in series with the new three-ohm line becomes $Z_L = Z_{ed} + Z_n =$ seven ohms.

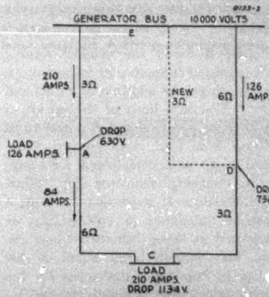

Figure 2. Addition of a new line

The current in the new line then becomes

$$I_n=\frac{E_d}{Z_L}=\frac{756}{7}=108 \text{ amperes}$$

and the correct voltage drop at point *D* becomes

$$E_{ed}''=Z_nI_n=3\times108=324 \text{ volts}$$

$$I_{ed}''=\frac{E_{ed}''}{Z_{ed}}=\frac{324}{6}=54 \text{ amperes}$$

$$I_{dc}''=I_n+I_{ed}''=108+54=162 \text{ amperes}$$
$$I_{ac}''=I_c-I_{dc}''=210-162=48 \text{ amperes}$$
$$I_{ea}''=I_a+I_{ac}''=126+48=174 \text{ amperes}$$

The corrected values of voltage are:

$$E_{dc}''=Z_{dc}I_{dc}''=3\times162=486 \text{ volts}$$
$$E_{ea}''=Z_{ea}I_{ea}''=3\times174=522 \text{ volts}$$
$$E_{ac}''=Z_{ac}I_{ac}''=6\times48=288 \text{ volts}$$
$$E_{ec}''=E_{ea}''+E_{ac}''=522+288=810 \text{ volts}$$

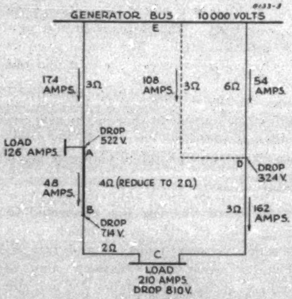

Figure 3. Change of impedance of a line

So that after adding these new superposed currents to the original values Kirchoff's laws are again satisfied. Since there are no changes in currents to the loads, this method can be applied when any number of loads are supplied at any number of points on the loop.

CASE 3. CHANGE OF IMPEDANCE OF A LINE

Figure 3 shows the original system with corrected currents and voltage drops resulting from the addition of a load and a line. The impedance of the section of line between points *A* and *B* is now to be reduced from four ohms to two ohms, which might be accomplished, for example, by changing conductor size. When this impedance is reduced two ohms, a fictitious unbalance in voltage can be considered as being introduced into the loop, this voltage being equal to the change in impedance multiplied by the current which was originally carried by that section of line, or $E_u=Z_rI_{ab}=2\times48=96$ volts. This voltage then divided by the new impedance of the entire loop gives the change in currents necessary to again satisfy Kirchoff's equations of current and voltage. When the impedance of a section is reduced, the current in that section increases and when the impedance of a section is increased, the current in that section will always be reduced. The added current in section *AB* then becomes:

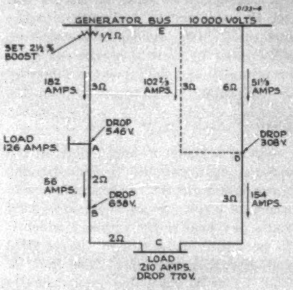

Figure 4. Change of transformer taps or regulator tap settings

$$I_L=\frac{E_u}{Z_L}=\frac{96}{12}=8 \text{ amperes}$$

and the corrected current in section *AB* is

$$I_{ac}''=I_{ac}+I_L=48+8=56 \text{ amperes}$$

also

$$I_{ea}''=I_{ea}+I_L=174+8=182 \text{ amperes}$$
$$I_{dc}''=I_{dc}+I_L=162-8=154 \text{ amperes}$$
$$I_n''=I_n+{}^2/_3I_L=108-(8\times{}^2/_3)=102^2/_3 \text{ amperes}$$
$$I_{ed}''=I_{ed}+1/3I_L=54-8/3=51^1/_3 \text{ amperes}$$

and the voltages are

$$\begin{aligned}E_{ea}''&=I_{ea}''Z_{ea}=182\times3=546 \text{ volts}\\ E_{ac}''&=I_{ac}''Z_{ac}=56\times4=\underline{224} \text{ volts}\\ E_c''&=\phantom{I_{ac}''Z_{ac}=56\times4=}770 \text{ volts}\\ E_{ed}''&=I_{ed}''Z_{ed}=51^1/_3\times6=308 \text{ volts}\\ E_{dc}''&=I_{dc}''Z_{dc}=154\times3=\underline{462} \text{ volts}\\ E_c''&=\phantom{I_{dc}''Z_{dc}=154\times3=}770 \text{ volts}\end{aligned}$$

CASE 4. CHANGING TRANSFORMER TAPS OR REGULATOR TAPS OR SETTINGS

Again figure 4 gives the corrected results obtained by changing a section of the line impedance and adding the necessary circulating current to again balance all currents and voltages. For the purpose of illustrating this fourth case, a step regulator at bus *E* in line *EA*, which is set to boost the line voltage there by $2^1/_2$ per cent or 250 volts, is assumed.

This is handled in the same way as the third case with the 250 volts acting on the impedance of the entire loop, except that in this case there is an increase in impedance in the loop instead of a reduction. The total impedance around the loop is now 12.5 ohms and, therefore, the changes in currents become 20 amperes. Corrections of the currents and voltages are made as in case 3. The only difference between the two cases is that the change of taps will produce this circulating current regardless of how much load is being carried, whereas in the case of the change of impedance in case 3, the change in current around the entire loop depends on how much load is being carried by the line section where the impedance change is made.

Accuracy of Methods

The foregoing examples, which were used merely to illustrate the methods, do not take into account the changes of phase angles of the load voltages with respect to the bus voltage. In the majority of power networks, the phase angles of the line impedance are greater than the phase angles of the load impedances and, therefore, the load voltages will lag the bus voltage. Any change on the system that causes an increase in voltage drop usually causes an increase in the phase angle between the load and bus voltage and in some cases introduces considerable error.

The simple case of a single load at the end of a line shown in figure 5, to which a second load equal to the first is added, will serve to show the effects of making changes on some of the common types of circuits serving the common types of loads.

Three cases, for which vector diagrams are shown in figure 6, are considered. In each case, the original load current is 100 amperes and the in-phase component of voltage drop is five per cent. In each case, the currents and voltages, obtained by calculation assuming both fixed impedance and fixed current, are shown as well as the values for loads made up entirely of motors as in group 2, those drawing a fixed kilovolt-ampere load as in group 1, and those made up of half load in group 1 and half in group 2. The reactive load current in group 2 is assumed to vary directly as the voltage. All values are referred to the voltage E_R. The errors that result from the two assumptions of fixed current and fixed impedance for each of the load groups are given in table II. Errors of voltage are expressed as a percentage of bus voltage and errors in current in

Table II. Percentage Errors Introduced for Various Loads by Assuming Constant I and Constant Z (Figures 5and 6)

Type Load	(a) Constant		(b) Constant		(c) Constant

terms of the correct value of total current in each case.

These examples involving voltage changes of more than five per cent at the load and voltage drops of more than ten per cent were chosen as representing very close to extreme conditions. Usually when the drop reaches ten per cent, it is necessary to make some change to provide good service and the change that is made does not usually reduce voltage drop more than five per cent for the total load. Hence the examples represent maximum conditions resulting in maximum errors. The examples show the errors that result when only a load is added to a system, but the addition of a line that will cause the same change in load voltage will give errors of the same magnitude.

In the first case (*a*), the phase angles of line and original load impedances are equal and, hence, there is no quadrature component of voltage or change of phase angle except where there are loads of the motor type. The load power factor is 60 per cent. This case represents one extreme, but is not very common on power systems.

The second case (*b*), is very common on networks made up of moderate-capacity circuits of voltages of 33 kv and less and on some circuits up to 66 kv. The original load power factor at the generator bus is 80 per cent and the ratio of R/X is $^1/_2$, so that the difference of the phase angles of the line and load impedances is 26.7 degrees.

The third case (*c*), is also rather common and is given here because it represents the other extreme beyond which the fixed current assumption leads to errors that definitely limit the use of these methods to special cases. The errors in voltage drop in this case are about the same as the errors introduced by assuming fixed impedances for loads, although the errors in current are still a good deal smaller than when the fixed impedances are assumed. The original load power factor at the generator bus is about 90 per cent and difference in phase angles of the line and load impedance is 45 degrees.

In all of the above cases, the error in total current is never more than a fraction of one per cent greater than the change in load voltage. Since the average cases are represented by cases (*b*) and (*c*), and the regulated type of loads are the most common loads, the presence of unregulated motor loads or loads of the resistance type will reduce both the magnitude and phase-angle errors of the load currents and voltages. The change in average load current on a network supplying a number of loads is always less than the maximum and, therefore, the errors will be smaller than those in the above table.

In the event that the errors in load currents or voltages are considered too great, which will be true of networks supplying regulated loads more than of any other, corrections can be applied to the load currents and the network recalculated. When corrections have to be made, the work is prolonged considerably, but one set of corrections will again give much closer results than when one set of corrections are made using constant impedance loads and can usually be more easily made. When changes in high-capacity, high-voltage circuits, are involved, it is necessary to deal with line impedances having a ratio R/X as small as one-sixth and loads of practically unity power factor. Calculations of such cases will result in very large errors unless some method employing successive corrections is used.

On many systems it is common practice to maintain a constant voltage on some major substation bus remote from the generating plant instead of at the generator bus. This substation is usually a central switching point for a number of high-capacity lines and control of voltage at that point gives some measure of voltage control over a large part of the system. When this is true, the voltage of this substation bus can be taken as a reference for calculating purposes. The variation of load voltages will be smaller taken with reference to this bus than when referred to the generator bus and the errors involved will be correspondingly reduced.

This practice is simulated in the previous examples of figure 5 by assuming that constant voltage is maintained at some point on the line between the load and generator rather than on the generator bus itself. The maximum change in load voltage may be only two or three per cent instead of five per cent previously considered and with these conditions the superposition methods can be extended to more of the high-reactance lines with high power factor loads without excessive error.

Typical Network Solutions

The procedure for the complete solution of an addition to an actual network and the results expected can be demonstrated with the network of figure 7 as an example.

The diagram represents a loop of 13.2-kv overhead lines supplying a number of loads to which a new line *EF* is to be added from the generator bus to a substation at *F*. Simultaneous readings of the original kilowatts and reactive kilovolt-amperes given in the following table were obtained at the points indicated:

	Kilowatts	Reactive Kilovolt-Amperes
Line *EA* at *E*	3,200	2,290
Load *A* at *A*	230	220
Load *B* at *B*	2,590	1,490
Line *BC* at *B*	220	190
Load *C* at *C*	430	180
Lines *EH* at *E*	7,310	5,250
Line *HG* at *H*	3,590	1,710
Load *G* at *G*	1,080	170
Load *D* at *D*	2,380	1,490

Using the kilowatt and reactive kilovolt-ampere readings in the table and

beginning at the generator bus, line current and voltage drop to the next load were calculated. Knowing the voltage at the next load, the load current there was calculated and referred in phase angle to the generator bus voltage and this process repeated until all of the currents and voltages on the original loop were known with reference to the generator bus voltage. These are the values shown on the diagram. The solution for all new currents and voltages after the new line is added then follows the method applied to figure 2.

Table III shows all values that applied to the original network, as well as three complete solutions based on the assumption that the loads acted as fixed values of impedance, current, and kilovolt-amperes respectively. The errors that result when all of the loads are regulated and calculations are made by methods assuming constant current and constant impedance respectively, are shown in table IV with voltage expressed in terms of generator bus voltage and current errors in terms of total corrected currents.

The relatively high average power factor of all the loads (84–85 per cent) on this network and the large voltage change which is a maximum at point *F* (6.7 per cent) make this example a rather severe test. The results when constant-current loads are assumed are within acceptable practical limits and are more accurate and much more easily obtained than when constant impedance is assumed.

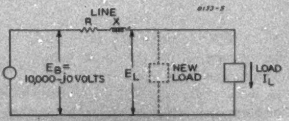

Figure 5. Single load at end of a circuit with identical new load to be added

A small amount of unregulated load, which is present on all networks, will bring the actual results closer to the calculated figures. The loop shown in figure 7 is a close approximation of an actual setup supplying a predominantly residential load, all of which was regulated. In spite of this fact, there were a small number of unregulated customer loads at points *A*, *C*, and *G*. Also during peak loads some of the regulators at stations *B* and *D* operated at full boost and probably allowed some drop in load voltage. With motor loads then at *A*, *C*, and *G*, and with 20 per cent of the load from stations *B* and *D* originally operating at a voltage two per cent below normal, the corrected total current to the entire network after the line addition would be 451 − j309.5, or 547 amperes. The percentage errors in the corresponding values obtained by superposition methods would be 1.6, 3.7, and 3.5 per cent respectively of the total current of 547 amperes.

Conclusions

The methods outlined here can be applied with a good degree of accuracy to many a-c networks, with the range of phase angles of both line and load impedances commonly found in operation. When they are used to calculate the effect of line changes that make up a part of a system between generating plants, other variables are introduced. The voltages on generating plant busses can often be assumed at a certain magnitude, but changes in phase angle introduce other factors that are difficult to handle by this method. When, however, the line change or addition makes up only a small part of the tie capacity between generating plants, the changes in angle between generators will be negligible and superposition can be applied. This is true of a large number of 13.2-kv and 33-kv lines on the Cincinnati Gas and Electric Company system where the capacity of one circuit is small compared to the total capacity of paralleled 66-kv and 13.2-kv lines.

It is recognized that the methods are not universally applicable to all problems, and that they are most useful for calculating additions to existing systems. On most subtransmission and distribution networks where a variety of types of loads are supplied, superposition methods will give a more accurate result than any of the others, unless a method of trial and error is used. There is no straightforward method of calculating exactly the general network, except where all loads act purely as fixed impedances and this is rarely found on power systems. Superposition methods are very direct where they can be applied and can be checked frequently in the course of one set of calculations. The reasons for the better accuracy of the superposition methods are:

(*a*). The original assumption that loads act as fixed currents simulates actual average conditions more closely than any other assumption.

(*b*). Calculations are made only of changes in values rather than of whole values.

(*c*). Fewer impedances are handled since the load values are omitted.

The method depends principally on getting a reliable set of load and voltage readings on the principal lines and loads, so that a complete operating condition can be set up before any changes are made. When, however, these data are available, these methods have a wide field of application on the moderate capacity circuits of the average power system. Many solutions are possible without making corrections because of the relatively small errors introduced by these methods and when errors become too great, the methods are well suited for making these corrections in many instances.

A Double-Break Oil- or Gas-Blast Power Fuse

G. LESLIE HILL
ASSOCIATE AIEE

Synopsis: The use of two fuse elements of different rating, in series, in a high-voltage fuse device is described in this paper. The two elements are placed in a tube and the tube is filled with an arc-extinguishing substance and sealed; one end with an expellable plug.

In operation the lower rated element melts first on an overcurrent and draws an arc; the energy from this arc is used to build up a pressure and forces the sealing plug out which establishes a second arc. Then the pressure in the tube blasts the arc extinguishing substance into the second arc and interrupts the circuit.

For convenience, the circuit-interrupting part of the device is built in the form of a cartridge refill for insertion in a fuse tube or holder. Seven years of field experience have been obtained and is reported in this paper. The device has been applied on circuits up to 60 kv.

About seven years ago, operating and field experience of the company with which the writer is associated, established a need for a dry-type fuse that would be interchangeable with a liquid-filled spring-actuated fuse which was in general use on the overhead distribution lines.

The specifications as set up by the operating staff were as follows:

(*a*). The fuse was to be dry type and easily refillable in the field.

(*b*). The fuse tube must be glass and not an organic material.

(*c*). It must be easily observed when blown.

(*d*). It must not expel long arcs either upward or downward when interrupting a circuit.

(*e*). It must not expel molten metal or fuse element parts.

(*f*). It must have sufficient interrupting capacity for general distribution lines and small substations; the tentative rating being set at 100,000 kva at 12,500 volts.

(*g*). It must carry its rated current continuously, if necessary, without deterioration and blow at a reasonable overcurrent.

A survey of the available fuse devices on the market did not yield any that would meet the above specification so authorization was given for the development of a device.

The writer, being interested in the circuit-interrupting art, had previously experimented with and developed various fuse devices* so the opportunity was given for the field application of the principle of circuit interruption used in the double-break fuse.

All of the requirements had been previously met in the experimental devices except (*b*) calling for the use of a glass tube on a dry-type expulsion fuse device. It was desired to use a glass tube for ease of visibility and to avoid the problem of carbonization from leakage current that would ensue if an organic tube were used.

Principle of Operation

Referring to figure 1 it will be seen that the two fuse elements, *A* and *B*, are in series with the tubular metallic conductor *F* between them. The element *A*, being lower rated than element *B*, fuses first and establishes a primary arc on overcurrent. The heat from this primary arc decomposes the arc-extinguishing substance surrounding element *A*, generating a gas which builds up a pressure in chamber *I*. The pressure thus obtained is directed against the conductor *G* and sealing member *J*, moving them outward and placing a tension on element *B*. When the tension exceeds the strength of element *B*, which is also weakened by the heat produced by overcurrent, it is easily pulled apart, causing a secondary arc.

With the establishment of the secondary arc in the orifice or mixing tube *K*, the gases previously generated and the arc-extinguishing substance are blasted into this space at a high velocity and in a turbulent manner. This causes a rapid deionization action to take place at the first current zero after the secondary arc has been established.

Expulsion and deionization are shown in figure 2, the gas blast from chamber I expelling all ionized gas and products of the arc, resulting in a clean deionized path through orifice *K*. When the sealing plug *J* and conductor *G* are expelled from the orifice, the flexible conductor *H* is carried away from the refill and into the bottom trap chamber, thus introducing sufficient insulation to prevent reestablishment of the circuit.

This method of arc extinction is employed in this fuse regardless of the magnitude of the current interrupted. An increment of time will always exist between the blowing of the two fusible elements, the increment decreasing as the current increases. Arcs created by moderate overcurrents will cause the pressure to build up at a slower rate than on large currents. However, when the pressure has been built up to a sufficient amount to establish the second arc, the circuit interruption is obtained in the same manner as on large overcurrents.

Tests

The actual functioning of the two arcs in series in a fuse tube on a 12,000-volt circuit was studied by suitably placing the two fuse elements within a heavy-walled glass tube and taking high-speed moving pictures. This showed beyond any question that the interaction between the primary and secondary arcs was as theoretically anticipated.

The distance actually required for the extinction of an electric arc is surprisingly small for a given voltage, if the space between the two electrodes is rapidly changed from a conduction path to a nonconducting path at the a-c zero. The method used to change the space between the two electrodes from conducting to nonconducting in this fuse device, does not depend upon the decomposition of the wall of the fuse chamber, under the heat of the arc, as in the typical expulsion fuse. But instead, the arc-extinguishing material surrounds both fusible elements and also fills the chambers, thus obtaining a quicker and more efficient deionizing action.

The length of the orifice *K* (figures 1 and 2) varied from three-quarters to $2^{1}/_{2}$ inches in the cartridge refills tested on a 12,000-volt circuit. The circuit interruption was entirely successful at any of the lengths within that range and no apparent difference in arc duration

---

Paper 40-134, recommended by the AIEE committee on protective devices, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted June 10, 1940; made available for preprinting July 18, 1940.

The author wishes to express his appreciation for the co-operation and helpful suggestions furnished by many individuals in the Pacific Gas and Electric Company. Especial appreciation is due the East Bay division for their willingness to be the first to place a sufficient number of the overhead dry-type devices in service, to obtain the initial field service, and the San Francisco division for their willingness to place the initial oil-filled fuses in service.

G. Leslie Hill is assistant engineer in charge of special engineering investigations, bureau of tests, department of engineering, Pacific Gas and Electric Company, San Francisco, Calif.

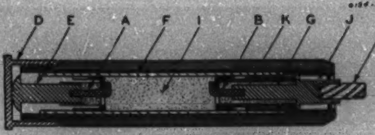

Figure 1. Cross section of the cartridge unit

The two fuse sections *A* and *B* are in series with the metal case *F* acting as the conductor between the fuse sections

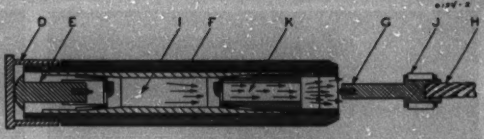

Figure 2. Cross section of the cartridge unit after a circuit interruption showing sealing plug being expelled from the end of the cartridge

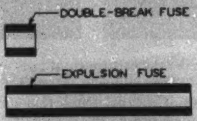

Figure 3. Approximate tube lengths required to interrupt a given voltage and current for the double-break fuse and the plain open-ended expulsion fuse

for a given current could be determined.

Figure 3 illustrates the relative distances required to successfully interrupt a given voltage and current by the double-break fuse and by the plain open-ended expulsion fuse.

When experiments were first made on the double-break fuse device, a spring was attached to the lower end of the conductor at the sealing plug *J*, figure 1, and extended to the lower ferrule. This spring was to aid in circuit interruption at moderate overcurrents. On heavy currents the expelled parts would be driven down into the spring and bent in such shapes as to prove, without question, the expelled members endeavored to drive the spring, rather than the movement being actuated by the spring. This led to the conclusion that the spring retarded the movement of the parting conductor rather than aid it.

Experiments were then made with the spring eliminated and it was found that the circuit was interrupted satisfactorily on moderate overload currents just sufficent to melt the *A* fuse element. The experiments were first conducted at 12,000 volts and later extended to 22,000, 39,000, and 62,000 volts.

It was thought by some engineers that two fuses in series would operate too slowly and that the blowing time between the two could not be co-ordinated so as to obtain the desired interaction of one arc upon the other. Sufficient tests have now been made and experience has been obtained to show that the interaction between the two fuse elements of different ratings, in a fuse tube, may be co-ordinated to a fairly high degree of accuracy.

It is readily recognized, from a study of the design shown in figures 1 and 2, that the pressure wave must travel from one end of the tube to the other end before the expellable plug is blown outward. It was also recognized that a granular material which would pack would not allow the pressure wave to pass, so tests were made to determine what the grading of the material should be.

The first material used had a large percentage of fines passing through a 200-mesh Tyler screen. This was soon found to pack and not allow the pressure wave to pass through at a rate sufficiently fast to prevent bursting of the tubes on heavy currents.

A coarser material was experimented with and at the present time the most suitable fineness for the granular material has been graded to pass a 60- and to be retained on a 100-mesh Tyler screen. This fineness is used in all the cartridges except the 14-inch length where the material is graded to pass a 60- and be retained on an 80-mesh screen. The percentage of voids in the −60+100 material is about 45 per cent and about 50 per cent for the −60+80 material.

Tables I and II give the arc duration, within the 14- and 7-inch cartridges, after the *A* fuse element melts and until the circuit is interrupted. This is for the "dry type" cartridge filled with a granular arc-extinguishing material. The total arc duration is divided into the primary arc time and the secondary arc time. The primary arc time represents the period required for the first arc to decompose a sufficient amount of the material, build up the pressure and blow the sealing member outward. The secondary arc time is that period required to interrupt the circuit after the second arc is started by the expulsion action of the sealing member being blown outward.

These data are obtained from the inspection of oscillograms taken during tests. On some of the oscillograms the point at which the second arc starts may be obtained by observing the rapid increase in the arc voltage but in other oscillograms this point is very difficult to distinguish. Where the total arc duration is of the order of one-half cycle or less, it was not practical to separate the two arc periods.

Figure 4 shows an example of an oscillogram taken of a double-break fuse interrupting 2,600 amperes at 12,500 volts,

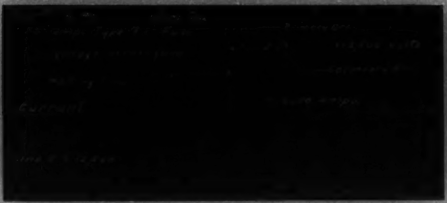

Figure 4. Oscillogram showing melting time of fuse element, primary and secondary arc time in a double-break fuse cartridge

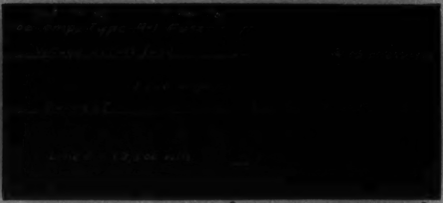

Figure 5. Oscillogram having melting time of fuse element, primary and secondary arc time all within one current loop in a double-break fuse cartridge

This film was selected to show the primary arc time of one cycle and then a secondary arc time of 0.45 cycle. It required two full cycles to melt the fuse. In figure 5 it will be seen that it is difficult to distinguish the periods of arcing. By an approximation, the primary arcing time may be taken as 0.35 cycle and the secondary time as 0.10 cycle. The melting time of the fuse in this test was 0.10 cycle.

The average values of arcing time for the 7- and 14-inch cartridges are shown graphically in figure 6. The time required for the primary arc to build up sufficient pressure to expell the sealing member and start the secondary arc is the difference between curves *A* and *C* for the 14-inch and curves *B* and *D* for the 7-inch cartridges.

The data for curves *A* and *C* were obtained on fuses rated from 5 to 100 amperes and the data for curves *B* and *D* were obtained on fuses rated from 2 to 200 amperes.

During the experimental tests and subsequent check tests on manufactured samples it was not found that the variation in the size of the *A* fuse (up to 200-ampere rating) had any appreciable effect on the arc duration or the circuit-interrupting ability of the device. It was definitely determined that the fuse device would not perform satisfactorily in "reverse", that is, with the *B* fuse smaller than the *A* fuse.

It has been interesting to inspect the interior of the refill cartridges after blowing, and to find practically no burning of the parts up to the higher currents tested, due to the decrease in the arcing time as the values of current increased. It has also been of interest to find that the *B* fuse in a great many cases had not been entirely burned away during tests where the current reached values as high as 2,500 amperes at 12,000 volts. This is a practical indication of the rapidity of the circuit interruption after the second arc is established when it is considered the *B* fuse is a lead-alloy wire about one-half inch long.

Experiments were made to determine the most suitable pressures that the primary arc should generate before the sealing member is expelled from the cartridge. The pressures could cover a fairly wide range and circuit interruption was satisfactory for moderate overcurrents and heavy short circuits. The range of the pressures varies from 50 to 90 pounds per square inch and applies to the short or long cartridges.

In addition to the circuit-interrupting tests covered in this paper, the double-break fuse met all the other requirements that a high-class device should meet such as:

(*a*). Radio interference on the various mountings.

(*b*). Current-carrying requirement that it should carry its rating.

(*c*). Freedom from corona.

(*d*). Exposure under the most adverse weather conditions.

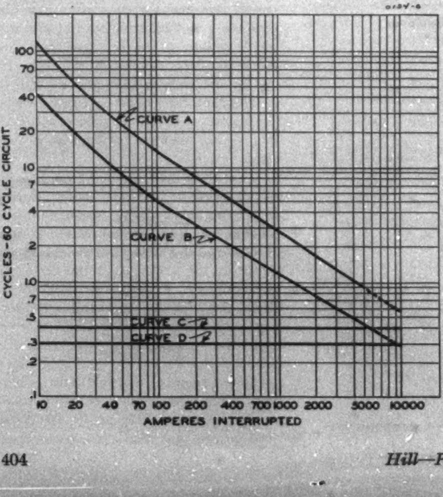

Figure 6. Arc duration within double-break fuse cartridges

Curve *D*—Average secondary arc time—7-inch cartridges

Difference between curves *A* and *C* and *B* and *D* is time required for primary arc to build up pressure

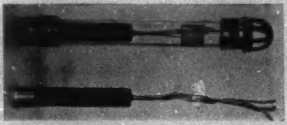

Figure 7. Dry-type double-break cartridge refill fuse in glass tube $11^1/_2$ inches center to center used on distribution circuits up to 22 kv

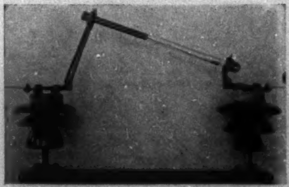

Figure 8. Dry-type double-break cartridge refill fuse in glass tube—used on 60-kv distribution lines—30 inches center to center for horizontal mounting

Figure 9. Interior of oil-filled cutout box used on 12-kv underground before modernization—using organic insulation and plain expulsion fuse

Moving pictures (64 frames per second) were taken of a large percentage of the circuit-interrupting tests and it was interesting to note the relatively small amount of arc gases emitted from the cartridges. There were seven tests at 62,500 volts where there was practically no visible arc and only two tests noted where there were more than two frames of visible arc duration in the pictures.

The greatest distance the arc was expelled out of the end of the tubes during any of the tests was two feet and most of the pictures show only two to six inches of arc out of the end of the fuse tube.

The tests were performed with power from various sources as follows:

(*a*). A three-phase 12,000-volt cable about five miles in length, utilizing iron-core and air-core reactors for limiting the current. Total power available from the line was approximately 100,000 kva.

(*b*). Synchronous condensers of 20,000 kva and 40,000 kva capacity.

(*c*). Water-wheel-driven generators of 15,000 kva and 12,500 kva capacity feeding through a transformer bank of 6,600/66,000 volts and 12,750 kva capacity.

Adaptation to Field Service

Figure 7 shows a dry-type double-break cartridge refill fuse used on distribution circuits up to 22 kv. The ferrules are two inches across the flats and are 11$^1/_2$-inch clip centers. A Pyrex glass tube is used instead of the usual organic insulating tube. One cartridge refill is shown inserted in the glass tube through the top ferrule, the cap of which acts as a clamping contact. Along side the fuse tube is a spare cartridge refill ready for insertion. The blown refill cartridges are accumulated in a central warehouse and then the internal fuse elements and extinguishing material are renewed. These fuses are built in sizes from 2 to 200 amperes.

Screwed onto the bottom ferrule is a perforated trap chamber which acts as a contact clamping means between the divided ends of the flexible conductor and the ferrule. The bottom trap chamber catches the flexible conductor and expelled parts from the cartridge and also aids in cooling any hot gases which may be expelled during blowing of the fuse. No tools are necessary for insertion or removal of the cartridge refill.

Figure 8 is the adaptation of the double-break cartridge refill fuse to 60-kv service. The fuse tube as shown is 30 inches, center to center of the clips, and the hardware is for horizontal mounting. The extended arm on one of the insulators is to place the closed end of the tube in a raised position to prevent rain from being blown in during a storm. The extended arm would be removed if the fuse tube were to be mounted in a vertical position; in this case the fuse tube is parallel with the channel-iron base. This fuse is built in sizes from 5 to 100 amperes.

The 60-kv fuse has been given a long-time fusing characteristic so that it is adaptable to transformer banks having reclosing oil circuit breakers on the low-voltage side.

Double-Break Principle Applied to Oil Fuse

The question of what fuse to use became quite a problem about five years ago when it was decided to modernize an oil-filled enclosed underground fuse switch that had been pioneered and developed in 1922 by the Great Western Power Company's system* in San Francisco. The interior of one of these original cutout boxes is shown as figure 9. The operating arms were of organic material and the fuse was of the open-end expulsion type with a fuse wire extending throughout its whole elngth, and fastened to the end ferrules.

The circuit-interrupting ability of this plain expulsion fuse, in an oil-filled cutout box, was very limited and the pressures set up in the box became quite high on relatively low currents so it was decided, in the modernization process, to install a higher-capacity fuse and also porcelain insulation on the operating arms and supports for the fuse terminals.

Figure 10 shows the interior of the improved cutout box with porcelain insulation and the new fuse. The fuse tube and refill cartridge are shown as figure 11. The cartridge utilizes the same principle of circuit interruption as the dry-type powder-filled cartridge shown in figures 1 and 2 except that oil is used as the filler inasmuch as the cutout box is filled with oil for insulation and for interrupting a load current when used as a manually operated switch.

It will be noted that the refill cartridge does not have an outer insulating tube surrounding the metal pressure tube *F* as it was found that the oil column surrounding this refill cartridge, when in-

*Now consolidated with the Pacific Gas and Electric Company system.

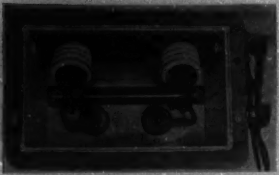

Figure 10. Interior of 12,000-volt oil-filled cutout box, after modernization using double-break oil-blast fuse and porcelain insulation

stalled in the fuse tube, had sufficient insulation to prevent flashback of the circuit around the insulating bushing on the expulsion end of the cartridge.

Table III gives circuit-interrupting test data of the double-break oil-filled fuse in an enclosed oil-fuse switch. These data cover a range of current from 5.6 amperes to 11,000 amperes at 12,000 volts. The tests were made on the design shown in figure 10. It was of interest to note that the arc time of the primary fuse *A* could not be separated from the secondary fuse *B* on the oscillograms as could be done in some of the oscillograms of the tests on the powder-filled devices. The maximum total arc time was only 0.6 cycle and the average total arc time was only 0.30 cycle on currents from 200 to 11,000 amperes. During the experimental tests, the maximum arc time was also only 0.6 cycle on currents as low as 160 amperes. Oscillograms were not taken during tests on the small currents of the order of five amperes, but the total time, including the melting of the fuse element, and the arc time was only a few cycles. The *A* fuse element in these tests was a number 40 advance wire.

Figure 12 gives the maximum pressures attained for interrupting various currents, at 12,000 volts, when the circuit is interrupted with a plain expulsion fuse and when interrupted with a double-break oil-blast fuse in a similar cutout box and similar circuit conditions. The double-break fuse interrupted approximately seven times as much current as the plain expulsion fuse, for a given pressure generated in the cutout box. It was of interest to note that there was no damage to the refill cartridge or fuse tube on currents as high as 11,000 amperes at 12,000 volts. The lid of the cutout box was not damaged until a current of 11,000 amperes was reached.

*No oscillogram taken; total interrupting time obtained by synchronous timer.

These oil-filled cutout boxes and the double-break oil fuse were developed quite hurriedly to meet a situation in San Francisco where a large number of 11,000-volt overhead lines had to be placed underground. The circuit-interrupting requirement was set at 10,000 amperes 12,000 volts. The experimental work, test on factory models, the final engineering drawings, and the first delivery were accomplished in approximately 90 days.

Field Experience

There have been about seven years' field experience on the dry-type double-break cartridge refill fuse, with a glass tube, on 12- and 22-kv service. This type is shown as figure 7. A trial batch of about 100 were first installed and watched rather closely. Within one year, enough circuit interruptions had occurred to show the design was functioning satisfactorily and up to the present time only very small minor changes have been made in the mechanical structure.

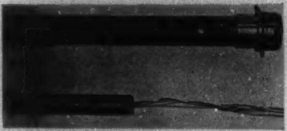

Figure 11. Oil-filled double-break fuse with refill cartridge used in 12,000-volt enclosed oil cutout box—oil film between refill cartridge and insulating tube prevents flashback during circuit interruption

Several thousand are now in service on the distribution lines and small substations. Examination of the refills, after blowing, show that practically 100 per cent may be used again by renewing the fuse elements and the arc-extinguishing material. This results in a very economical arrangement. The service men like the refill feature as it saves space in their truck. A few glass tubes may be carried and enough refills to meet the service requirement.

The fuses, with the glass tubes, were first restricted to circuits having a maximum short-circuit current of 4,000 amperes at 12 kv but are now installed on distribution circuits where reactors limit the maximum short-circuit current to approximately 7,000 amperes.

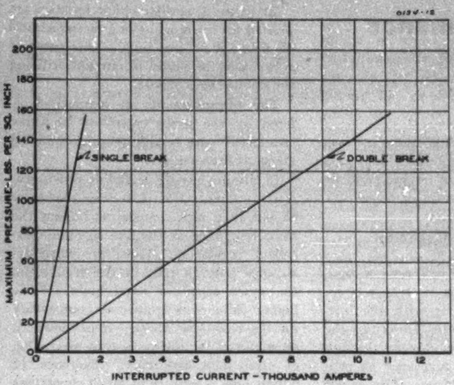

Figure 12. Maximum pressures obtained using plain expulsion fuse and double-break fuse in an enclosed oil-filled cutout box

There has been about four years' experience on the 60-kv fuse shown as figure 8. About 200 have been installed to date and cartridge refills are returned to the central warehouse for renewal, the same as the refills for the lower-voltage devices.

About 700 of the double-break oil-blast fuses have been used in new enclosed oil-filled cutout boxes in the 12-kv underground distribution service to date. The blown cartridges are returned to the central warehouse for renewal of the fuse elements and refilling with oil. The cartridges are then returned for service, in the field, the same as the dry type.

Additional Experimental Work

When it is analyzed that the circuit interruption takes place within the cartridge of the double-break fuse, it is realized the glass tube is simply a container and a means of connection to the circuit. Experiments have been made with the dry-type double-break 60-kv cartridge mounted without a glass tube and utilizing a stainless-steel retracting spring arm to give an air break clearance after the fuse blows. This device is shown in figures 13*a* and 13*b* and has been tested up to 400 amperes at 60 kv and 4,000 amperes at 12 kv. Moving pictures show a remarkably small amount of arc gases emitted and a relatively small amount of "mushrooming" back around the end of the cartridge. If this structural arrangement proves successful in service, it will make a very economical device and at the same time have desirable circuit-interrupting characteristics.

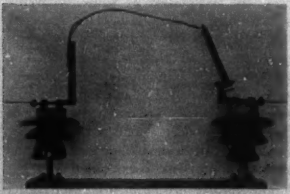

Figure 13a. Experimental double-break cartridge fuse mounted without glass tube—utilizing a stainless-steel retracting spring arm

The remarkable short arc time characteristics of the double-break oil-filled fuse has led to the consideration of using a noninflammable liquid in the type now using dry granular arc extinguishing material. Some tests have been made and practical difficulties will have to be overcome, such as sealing, etc., but if adopted, we would have the novel feature of a liquid-filled "dry type".

The requirements as originally set up for the devices for our distribution lines may be classed as an intermediate design as to interrupting duty, costs, etc. If a higher interrupting capacity should be desired, detail structural features of the double-break oil or gas-blast fuse may be changed to meet the requirements.

Conclusions

The various modifications of the double-break fuse, shown in this paper, have met the service need and requirements as set up for our overhead and underground distribution lines and they have proved to be high-class economical fuse devices.

When arc-extinguishing substances are confined and then released at a predetermined pressure, as in the double-break fuse, the volts interrupted per inch are much higher than in fuse devices such as open-ended expulsion fuses. The ratio of length, for a given circuit condition, may vary from 1:2 to 1:7 depending upon the device used for comparison.

The distance the arc gases are expelled and the volume of gases expelled from the double-break fuse have been found to be considerably less than other types of expulsion-fuse devices, when tested under the same circuit conditions.

The duration of the arc time, after the second arc is established, has been found to be of the order of one-half cycle or less for all voltages up to the highest tested which was 62,500. Thus the expelled arc gases, during circuit interruption, are of the same general magnitude for a given current, regardless of the circuit voltage.

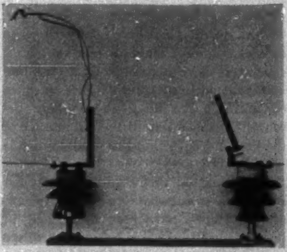

Figure 13b. Experimental double-break fuse, without glass tube—retracting spring arm giving air clearance after blowing

The total arc time of the double-break oil-blast fuse (that is, the duration of the primary arc to build up the pressure and the duration of the secondary arc to interrupt the circuit) is the shortest of any expulsion fuse device tested by the writer, for a given circuit condition.

The total arc time of the dry-type double-break fuse, using a granular filler, is comparable to the type of expulsion fuse devices utilizing large springs to aid in circuit interruption except on currents where the pressure generated by the primary arc is required to break the second fuse mechanically in order to establish the second arc.

Tests and field experience have proved that glass tubes may be used as fuse tubes in the dry-type double-break devices where the circuit interruption takes place entirely within the refill cartridge inserted within the glass tube.

Capacitors and Circuit Performance

J. W. BUTLER
MEMBER AIEE

CONSIDERABLE literature has appeared in the technical press during the past few years describing and analyzing the application of capacitors. Naturally, each author has treated the particular phase of the subject that best accomplished his objectives. It is felt, however, that a large majority of the potential users, and probably a good many of the actual users of capacitors, do not fully appreciate the change effected in the fundamental circuit characteristics when capacitors are applied. And the literature referred to does not seem to supply the demand for this type of information. This opinion has evolved through answering such queries as: "What should I use here, shunt or series capacitors?" "Should I put on shunt capacitors or regulators to fix up my bad voltage condition?" and "I guess a series capacitor is the thing to use here because it *balances* out all the inductance of the line and with that out, the voltage is bound to be good."

It is admitted that conditions may exist, in a somewhat restricted sense, wherein the alternatives mentioned in the two questions could be used, or where a series capacitor would perform as postulated. However, a knowledge of the conditions inspiring the inquiries showed that the effect on circuit performance of the suggested applications of capacitors was not thoroughly understood.

This paper analyzes the performance of circuits with different types of capacitor applications. By circuit performance is meant: voltage regulation, voltage level, voltage control, load division, power factor, and energy losses. These points are analyzed and discussed as they are influenced by both series and shunt capacitors. The field of application of capacitors, in distribution and transmission circuits is fairly well indicated in this paper, as far as circuit performance is concerned. The economic picture obviously will have its influence in a specific solution, and the information offered herein should make it easier for one to evaluate the results he expects to obtain in the way of circuit performance from the installation of capacitors.

Part A—The Series Capacitor

The series capacitor is simply a *negative* (capacitive) reactance, which is inserted directly in series with the line. Conventional definitions describe the effect of lagging current flowing through a *positive* (inductive) reactance as producing a drop in voltage. This effect is recognized as the usual garden variety of voltage drop experienced where current flows through distribution feeders, transformers, feeder reactors, etc. Conversely, when lagging current flows through a *negative* reactance, such as a series capacitor, a corresponding rise in voltage is obtained. It is this rise in voltage provided by the series capacitor which compensates more or less for the regulation and power-factor reductions effected by the inductive reactance of the line, transformers, etc. in the circuit.

1. Effect on Regulation

Since a series capacitor is a *negative* reactance, it is apparent that its judicious use can materially reduce the effective, or equivalent, impedance of a transmission or distribution circuit. With a reduction in the circuit impedance, it naturally follows that there will be less voltage variation or voltage regulation experienced when power is transmitted over the circuit. The effectiveness of a series capacitor in improving regulation may be clearly appreciated by merely calculating the regulation of a given circuit for various load power factors as the reactance is reduced to zero or even made negative. Such calculations, for demonstration purposes, have been made for two circuits and the results are shown plotted in figures 1 and 2.

In figure 1*a*, the dashed curve gives the regulation for a line having an impedance of $0.05+j0.20$ per unit, for various power factors from 0.6 to 1.0. This ratio of x to r may be found in circuits utilizing the larger wire sizes. Improvements in regulation obtained by reducing the reactance of the circuit to zero then to $-j0.05$ are shown in figures 1*b* and 1*c*, respectively.

In figure 2, similar characteristics are plotted for a circuit having an impedance of $0.15+j0.05$ per unit. This ratio of x to r may be found in circuits utilizing the smaller sizes of wire.

The improvements in regulation offered by the series capacitor for these two circuits are readily seen by a casual glance at these curves.

In circuits having negligible resistance, it is apparent that it is only necessary to put in a series capacitor having the same reactance as the line to obtain excellent regulation. However, when resistance plays a part in the regulation, the series capacitor must have a little higher value of reactance to compensate for the resistance drop. It is shown in appendix *A*, equation 7, that the value of equivalent reactance (reactance of circuit plus reactance of series capacitor) to give zero regulation is a definite function of the circuit resistance and load power factor. This relation is plotted in figure 3 which enables the ready determination of the equivalent reactance and hence the reactance of the series capacitor when the line resistance and load power factor are known. For example, suppose the resistance r' is 0.1 per unit, and the power factor is 0.7, from the curve it is read that x' must be -0.114 to have zero regulation. Then x_c will be 0.114 plus the reactance of the circuit, whatever its value might be.

It is interesting to note that there is a definite limit in power factor, for a given value of resistance at which zero regulation can be obtained. For instance, where $r'=0.1$, zero regulation cannot be obtained where the power factor exceeds 0.9. This limitation, however, has no practical significance at the present because such over-compensation of the line would make regulation very critical to changes in power factor.

Since a series capacitor is a *lumped* negative reactance, it produces all of the rise in voltage immediately at its location. Abrupt changes in voltage of this character, although in the opposite direction, are recognized as those occurring at a feeder reactor. It is thus seen that the voltage on the *load* side of the series capacitor is all that is affected. The voltage on the source side is unchanged; hence the so-called "balancing out the reactance" is effective on the load side of the capacitor only. This attribute may or may not be desirable, depending upon the local conditions, as explained later.

The voltage profile of a certain feeder with and without a series capacitor is shown in figure 4. It should be noted that the voltages between the source

Paper 40-126, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted June 24, 1940; made available for preprinting July 11, 1940.

J. W. Butler is in the central-station engineering department of the General Electric Company, Schenectady, N. Y.

and the equipment is unaffected by the series capacitor, while the voltages beyond the installation are greatly improved. The series capacitor acts exactly like a branch or feeder regulator in this respect.

2. Effect on Power Factor

A series capacitor at rated load provides power-factor improvement to the same degree as the same amount of capactive kilovolt-amperes does, connected in shunt. It is interesting to note in this respect that a series capacitor accomplishes power factor improvement by providing an out-of-phase component of voltage as compared to the shunt capacitor accomplishing the same improvement with an out-of-phase component of current. These points are demonstrated by the vector diagrams of figure 5. In figure 5*b*, it is seen that the voltage across the series capacitor, E_c, acts in a way as to reduce the angle between the load current and the voltage on the source side of the capacitor. Hence the power factor on the source side is reduced since the cosine of this angle is the power factor. This point should be considered when predicting the performance of cascaded series capacitors that may be used in long distribution feeders. It should be noted here that this power-factor reduction does not release thermal capacity nor reduce line losses until the current has passed through a regulator where the proper transformations are made. However, voltage capacity of the line and regulating range of the regulator is released, which many times are the limiting factors in overhead lines.

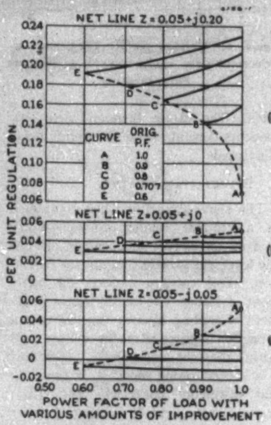

Figure 1. Voltage regulation

Dashed curves give regulations of different circuits for constant kilovolt-ampere load at different power factors. Solid curves give regulations for same conditions as various initial load power factors are improved by unswitched shunt capacitors. The net line impedance of *b* and *c* represents initial line with appropriate series capacitor

In the ordinary application for voltage improvement, sufficient capacitive kilovolt-amperes is not used to effect a sizable power-factor improvement. Nevertheless there are loads of such a nature as to allow power-factor improvement with series capacitors to be economically and automatically accomplished. This method in brief involves putting in a series capacitive reactance equal to the inductive reactance of the load and bus work. Then the current that flows is limited only by the load resistance—hence the circuit power factor is always unity. Thus reactive kilovolt-amperes, or power-factor improvement, is automatically provided strictly as a function of the load with no moving parts or switching, as would be required with shunt capacitors. So far these applications have been limited to welding and resistance-furnace loads. These applications are discussed later.

3. Effect on Voltage Level

Voltage level is generally referred to as describing the average voltage over a line from the substation to the end of the line. The series capacitor can raise this voltage level only insofar as it is effected by the voltage drop in the line itself. The series capacitor provides a voltage boost proportional to its reactance and the load current passing through it. This characteristic causes the voltage improvement or boost to appear independently of the magnitude of the circuit voltage; that is, the substation voltage of the circuit does not influence the voltage rise provided by the series capacitor. This means that the series capacitor cannot correct for substation voltage variations that occur independently of the load on the substation. In the practical case, however, this is not usually interpreted as a serious limitation, but it should be recognized when the series capacitor is being installed for regulating voltage for the daily load cycle, instead of regulators.

4. Applications of the Series Capacitor

(*a*). *For Improving Voltage Regulation.* Fluctuating, intermittent, and suddenly applied loads corresponding to motor starting, log sawing, resistance welding, etc., cause voltage fluctuations that can be and are very objectionable. It has been to circuits of this type that the series capacitor has been mostly applied up to the present time. These rapid voltage changes are automatically and instantaneously corrected by the series capacitor. The series capacitor in providing these instantaneous, automatic voltage improvements as a function of the load and power factor holds a unique position in its field. The voltage improvement offered for this type of application is demonstrated in the curves of figure 4. From these curves it is seen that a very good voltage condition exists throughout the line beyond the series capacitor during normal load conditions as well as when the motor is started which was causing bad voltage fluctuations.

Since a series capacitor provides an *abrupt* voltage rise and not a gradual rise in the circuit, and further since only certain regions of the circuit can obtain substantially zero regulation, it follows that under certain circuit conditions the solution offered by the series capacitor may not be acceptable. For example, the voltage of a long feeder supplying a reasonably uniform distributed load along its length and a large fluctuating load, such as a saw or rolling mill at the end, would be difficult to fix up with a single

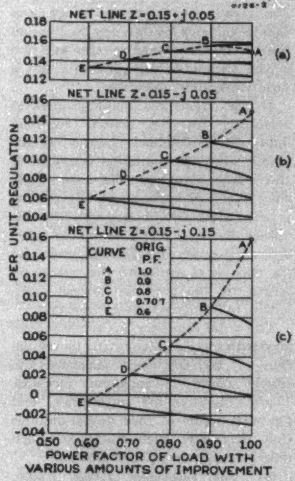

Figure 2. Same as figure 1 except line impedances are changed

series capacitor. The conditions existing in this type of application are shown in the curves of figure 6. Here it is seen that the consumers on the source side of the capacitor get no relief while those on the load side adjacent to the capacitor get a sudden rise in voltage which may still cause light flicker. The regulation then decreases gradually toward the end of the line until a point is reached where the line impedance plus the series capacitor reactance would be of such a value as to give substantial zero regulation. The better application is obviously the one wherein the load is taken from the circuit where the minimum regulation can be obtained or, saying it another way, a circuit wherein the acceptable low values of regulation can be obtained in the region on the circuit where most of the load is served. Since a series capacitor acts exactly as a regulator in this respect, a good preliminary test as to the feasibility of a proposed application is the question "Would the problem be satisfactorily solved by an induction or step regulator that could automatically and instantaneously assume its new position as dictated by the new load condition?" If the answer to this question is yes, then it is very probable that a series capacitor is applicable.

If the regulation problem involves correcting for the normal everyday light-load to full-load changes on the circuit, then the limitation described in the above paragraph may not apply since the load increases or changes are gradual which do not cause objectionable voltage flickers. There have been a few series capacitor installations made for the purpose of regulating the voltage required by the everyday normal light-load to full-load changes on the circuit.[1]

The series capacitor has recently been used with success in improving the regulation of high-frequency generators to supply power to induction furnaces. These generators are single-phase, and the very nature of their design dictates that they have high reactance which reflects itself in very poor regulation.

(*b*). *For Improving Power Factor.* The use of series capacitors for this service has been limited so far to welding and resistance-furnace installations. Applications of this nature have been reported by Marbury-Levy[2] and Levoy.[3] In each of these applications the series capacitor is tuned to the reactance of the bus work, furnace, etc., or the welding transformer, and its secondary circuit, thus forming a substantially unity-power-factor circuit. The supply voltage is, of course, reduced from the value used before the installation of the capacitor since the current is substantially resistance limited. It is felt that these types of applications have a great future, since the use of electricity is playing a larger and larger part in welding and metal reduction processes.

(*c*). *For Improving Load Division in Parallel Circuits.* The operation of parallel circuits having widely different impedances may become unsatisfactory from the standpoint of load division. The series capacitor can be used to alter the impedance of one or more of the circuits in order to secure the desired division of current. In fact, it was to this use that the first series capacitor was put in transmission circuits.[4] It is of interest to note further that it is possible to apply series capacitors in two parallel circuits to obtain a prescribed division of load and at the same time obtain substantially zero regulation at the receiving end. An application of this type recently arose which involved a voltage flicker and load division problem resulting from an arc-furnace load being supplied through an underground cable and an overhead line.

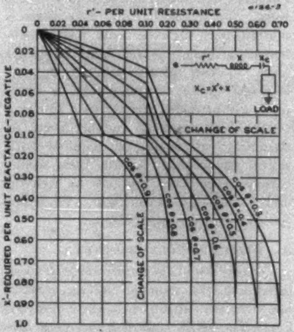

Figure 3. Curves for determining necessary reactance to give zero regulation as a function of line resistance and load power factor

Part B—The Shunt Capacitor

The so-called shunt capacitor is simply a capacitive reactance connected on an electric circuit in shunt with the loads on the circuit. This piece of equipment can be considered merely as another load on the circuit with its own peculiarities or as a change that has been made in the impedance of the line supplying the other loads. The choice between these two concepts depends upon the points being illustrated.

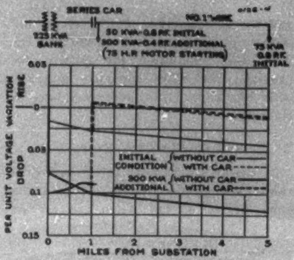

Figure 4. Voltage profile—illustrating improvement from application of a five-ohm series capacitor

1. EFFECT ON REGULATION

The shunt capacitor when considered as a *constant* leading kilovolt-ampere load on the circuit, independent of voltage level, has no effect on voltage regulation. This concept neglects the increment of voltage rise caused by the increment of leading kilovolt-amperes that a capacitor requires when the voltage rises during the light-load periods. Since this is a second order effect, it is generally and justifiably neglected. The effect, however, may actually be that of either increasing or decreasing the regulation, depending upon the amount of resistance in line. Since this effect is fully treated in part *C* of the paper, wherein the effect of using shunt and series capacitors together is discussed and analyzed, it will not be repeated here.

2. EFFECT ON POWER FACTOR

The shunt capacitor is fundamentally a power-factor improver. Any benefits that can be derived in a system by improving the power factor can, therefore, be realized by properly utilizing the shunt capacitor. The several particular responses of a system through the improvement of power factor will be discussed below in the application section, and since the fundamentals of power-factor improvement are so well known, they will be only briefly outlined here.

The vector diagrams of figures 5*a* and 5*c* indicate the manner in which shunt capacitor current or kilovolt-amperes combines with the load current or kilovolt-amperes to effect an improvement in power factor. The equations defining these diagrams are given in appendix *C*. In order that the reader may readily obtain a concept as to the power-factor-improving ability of capacitive kilovolt-

---

1. For all numbered references see list at end of paper.

amperes for different load power factors, the curves of figure 7 have been plotted from equation 17. These curves show the relation between the capacitive kilovolt-amperes added at any original power factor to the improved power factor. For example, the heavy line (figure 7) shows the improvement in power factor of a 0.6 power factor load as capacitive kilovolt-amperes is added. In order to improve to 0.9 power factor, 0.5 per unit of the original load kilovolt-amperes in capacitive kilovolt-amperes, must be added. These curves are the usual data plotted in slightly different form.

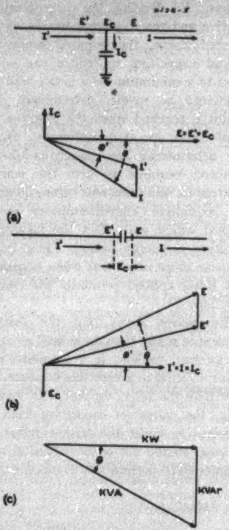

Figure 5. Vector diagrams

Illustrating relation of:

(a)—Voltage, current, and power factor with shunt capacitors

(b)—Voltage, current, and power factor with series capacitors

(c)—Kilowatts, kilovars, and kilovolt-amperes for the general case

3. Effect on Voltage Level

When studying the effects of the shunt capacitor in raising the circuit voltage, the concept of considering the capacitor as a fixed load of leading power factor proves helpful. Neglecting resistance in the circuit, the voltage rise caused by I amperes of leading current flowing through X ohms of inductive reactance is IX volts. If the line reactance is expressed in per unit, with the capacitive kilovolt-amperes as a base, this rise in voltage is simply equal to the per unit reactance. For instance, if a 180-kva capacitor bank is connected on a four-kv three-phase circuit so that its current flows through two ohms of reactance, what will be the voltage rise? Changing the two ohms to per unit, on 180-kva base by equation 14, there is

$$X = \frac{2(180)}{(4)^2 1{,}000} = 0.0225$$

which says that a rise of 0.0225 per unit of normal voltage will result when base current (that corresponding to 180 kva) flows.

Since the line reactance is independent of any other loads on the circuit, and since the capacitor current is also independent (this neglects small variations in current due to the voltage changes caused by other loads on the circuit) of the other loads, it follows for practical purposes that the voltage rise effected by capacitors is a constant and fixed value. This point should be kept in mind when applying capacitors for purposes of voltage improvement in order to alleviate objectionable voltages during light load.

In order to demonstrate clearly this type of voltage improvement, the curves in figure 8 have been prepared. A feeder is taken that supplies five equal loads distributed along its length and the secondary voltage conditions obtaining from three methods of operation are illustrated.

Original Condition. The regulator is connected to give ten per cent boost and no buck. At full load the voltage is ten per cent high at the substation and ten per cent low at the end. At no load the voltage is normal over the complete circuit. The regulation, as defined in this paper, varies from ten per cent at either end to zero one-third the distance out from the substation.

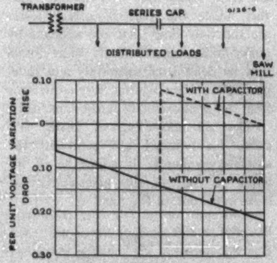

Figure 6. Voltage profile

Illustrating voltage conditions caused by fluctuating load at the end of a line. The voltage served to distributed loads may or may not be satisfactory, while voltage at the load is good

With Shunt Capacitors. By adding sufficient shunt capacitors at the end to obtain a ten per cent rise, the regulator can be connected to operate over a range of five per cent buck or boost. Then at full load the regulator is in full boost at five per cent, and the voltage profile is as illustrated in the curves, with the voltage up at the end five per cent above the original condition. At no load the voltage is five per cent below normal at the source and it is five per cent above normal at the far end. The regulation again varies from ten per cent at either end to zero one-third the way out on the feeder.

With Line Boosters or Taps on the Distribution Transformers. The permanent voltage boosts provided by the shunt capacitors at each load location may be simulated by line boosters (autotransformers) appropriately located or by taps on the distribution transformers. In the case at hand, each transformer is set on a tap to give a $2^1/_2$ per cent boost to the secondary voltage and again the regulator can be reconnected to operate over a ±5 per cent range.

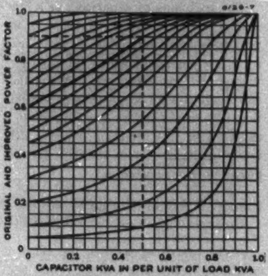

Figure 7. Power-factor improvement—curves for determining necessary per-unit capacitive kilovolt-amperes to effect a prescribed improvement

Example—Original power factor = 0.6, desired power factor = 0.9, required capacitive kilovolt-amperes = 0.5 per unit of original load kilovolt-amperes

Comparing these results with those of the shunt capacitor, it is seen that

(a). The average voltages over the line under all conditions of load are the same.

(b). The regulations at any point in the line are the same.

(c). The regulators operate over identical ranges.

There is no doubt that a better choice of taps or location of capacitors could be made to effect a better over-all practical voltage condition than that shown, but this case is merely given to illustrate the principle under discussion. Capacitors are valuable and useful in performing this type of voltage improvement because taps are seldom available on transformers in areas requiring improvement. Even if taps were available, a practical complication may result through the necessity of properly setting taps on transformers where transfers, changes, or additions are being made. Then, of course, it should not be forgotten that capacitors offer many other well-known benefits through power-factor improvement that transformer taps and boosters cannot provide. This example is cited in an attempt to portray clearly these voltage improvements in terms that are so familiar to distribution engineers. If this picture were kept in mind when applying capacitors, overvoltages at light load would not be a problem.

The switching of capacitors as a function of voltage, current, or time, for improving voltage regulation is being used by a few engineers, where the light-load voltages become excessive. This method of voltage control seems to offer possibilities, and in the future great progress is expected in this direction, since it definitely increases system stability and improves voltage regulation.

EFFECT OF RESISTANCE ON VOLTAGE RISE

In the preceding section, the effect of resistance in limiting voltage rise is neglected. This point is briefly investigated in the interests of clarity and completeness. The following expression for the sending-end voltage, including resistance, is derived in appendix *A*:

$$e_s = [e_r^2 + (iz')^2 + 2e_r i(r' \cos \Theta + x' \sin \Theta)]^{1/2}$$

Defining the voltage rise V_r as the difference between e_s and e_r with e_r normal, and changing the constants to per unit on the capacitor kilovolt-ampere base, the following expression is obtained for zero leading power factor

$$V_r = (1.0 + x'^2 + r'^2 - 2x')^{1/2} - 1.0$$

In order to evaluate the effect of resistance in this expression, a three-phase four-kilovolt circuit one mile long with 100 capacitive-kilovolt-ampere connected at its end is taken. The voltage rise for various wire sizes, all having an equivalent spacing of 36 inches is shown plotted in figure 9. It is found that the resistance has no perceptible effect up to wire size number 1, and that the effect is negligible up to and including number 4 wire. The curve was carried on out to number 10 wire in order to complete the picture and it is seen that resistance begins to show its effect around number 7 or number 8 wire.

Since the per-unit impedance constants in the above equation for V_r vary directly with the length of the line and the capacitive kilovolt-amperes, the results in figure 9 may be considered as applying to 100 capacitive kilovolt-ampere miles. This may be 100 capacitive kilovolt-amperes on one mile, 50 capacitive kilovolt-amperes on two miles, etc. With this concept, the rise attributable to any given length of line and capacitive kilovolt-ampere in question may be obtained by merely dividing the capacitive kilovolt-ampere miles by 100 and multiplying it by the per unit rise given by the curve in figure 9, for the size of wire in question.

4. EFFECT ON RESISTANCE LOSSES

The resistance loss in a circuit is equal to the product of the resistance and the current squared. The current, in turn, is equal to the r.s.s. (root of the sum of the squares) value of the reactive and active components of current. Since the loss is a function of the current squared, it follows that the loss due to the two components of current may be reckoned separately—thus

$$\begin{aligned}\text{Total loss} &= R[(I \cos \Theta)^2 + (I \sin \Theta)^2] \\ &= \text{active-current losses plus reactive-current losses} \\ &= W_a + W_r\end{aligned}$$

This concept in figuring losses is useful since the active-current losses are not affected by power factor and these losses represent the absolute minimum to which the total losses may be reduced. Further, since the reactive-current losses are the only ones that are affected by power-factor improvement, these losses may be dealt with separately and independently, when figuring loss reductions from the application of shunt capacitors.

Since the active-current losses, W_a, cannot be reduced, and represent the absolute minimum, it might be of interest to express the reactive-current losses in per unit of W_a, thus

$$\frac{W_r}{W_a} = \frac{R(I \sin \Theta)^2}{R(I \cos \Theta)^2} = \tan^2 \Theta$$

This ratio tells directly what fraction of the absolute minimum circuit loss is being produced by the reactive current. This relation is shown plotted in figure 10, from which a visual picture may be readily obtained of the loss-producing ability of reactive current as a function of power factor.

In a practical case, the total energy loss, that is, the kilowatt-hour loss over a given period, is the figure that is usually of major importance. Therefore, the load cycle, the daily load pattern, must be considered in order to get an accurate picture. Since the losses vary as the square of the load, the rms value of the load current over a given period should be determined for accurate loss calculations. By dividing the current into its active and reactive components, as suggested above, the required amount of shunt capacitors to reduce the energy loss to a minimum for a given load pattern can be readily determined. This point is reached when the reactive current losses are at a minimum. Hence, by determining the capacitive kilovolt-amperes required to give the reactive current its minimum rms value, the value of capacitive kilovolt-amperes is obtained which will effect the largest reduction in energy losses. These points become more important when capacitors are being applied primarily for loss reductions.

Experience shows that the reactive current in many systems as well as in the component feeders, is reasonably constant, at least to a very much greater degree than the active current. In view of this, the value of capacitive kilovolt-amperes to effect the largest reduction in losses should not be as critical as may be inferred from the above discussion.

5. APPLICATIONS

The applications of shunt capacitors are so numerous and varied and they are proved in by so many different points of view, that this paper will merely mention, for completeness sake, the major fields of application.

(*a*). *For Releasing Capacity.* The releasing of capacity in cables, substations, generators, etc., where current loading is the limiting factor, seems to have been the basis for the installation of a major part of shunt capacitors applied to central station systems in this country.[5] It is the general rule that a steam turbine has sufficient kilowatt capacity to allow the generator to deliver its full kilovolt-ampere output at unity power factor. This is, however, many times impossible to accomplish in an emergency because the generator may be loaded up with reactive. The shunt capacitor has proved invaluable on several occasions by supplying this reactive and leaving the generator free to grind out kilowatts.

Such applications for releasing system capacity in general and postponing large investments in substation equipment are somewhat obvious and with the advances in manufacturing and design technique that have been and will be accomplished, the capacitor promises to become a major piece of system equipment.

(*b*). *For Reducing Power Costs.* Many power companies today have rate structures that effectively pay a bonus to those consumers improving their load power-factor to within certain prescribed limits. This policy began at about the turn of the century, at which time the effects on system performance of reactive kilovolt-amperes were being realized.

The following extracts are taken from the *Proceedings* of the 30th convention of NELA held in Washington, D. C., June 1907, pages 81–3:

> "With the rapid increase in the industrial use of induction motors and in arc lighting by alternating current, the troubles incident to low power factor, in systems not designed for it, have become unfortunately familiar."
>
> "Low power factor has two serious results: it limits the capacity of the electrical part of the system by loading it up with unproductive current—current for which no revenue is obtained; and it means poor voltage regulation."
>
> "The rating of electrical apparatus depends primarily on the heating produced by the load, and this heating depends entirely on the current. The kilowatt load, therefore, unless the corresponding power-factor is taken into account, is not a measure of the actual load on the apparatus."
>
> "The second injurious effect of low power factor is poor voltage regulation. This effect is well known and requires no extended explanation."

These injurious effects of reactive kilovolt-amperes being realized by the public utilities and the resultant power-factor clauses in rate structures having been put into effect, have made it possible for capacitors to effect untold savings to industrial consumers of electricity. A few reports on installations of this nature are listed at the end of the paper.[6]

(*c*). *For Reducing Energy Losses.* The reduction of energy losses has in many instances been the deciding factor in justifying shunt capacitors. Independent companies purchasing energy can place a definite evaluation on line losses, which makes it merely a matter of arithmetic to figure the savings. Operating companies, however, find this procedure a little more elusive, since line-loss evaluations vary in different parts of the system and even then personal opinions play such an important role.

Power-factor improvement, however, is accompanied by a definite reduction in transmission and distribution losses, and each individual case must be treated on its own merits.

(*d*). *For Improving Voltage.* Many users of shunt capacitors have reported voltage improvements of sufficient magnitude to justify capacitors on that basis alone. This, of course, depends upon the specific circumstances surrounding the case and the evaluation of the improvement, but the fact remains, capacitors can and do effect voltage improvements that are accompanied by many other well-known related benefits, which generally make their installation very attractive.

The use of capacitors switched in banks for regulating high-line voltages instead of synchronous condensers is another field which has only been touched in this country. On the continent this application has attained major proportions and it has promise of developing in this country in the near future.

Part C—The Series and Shunt Capacitors Together

The shunt capacitor is so popularly used today that more likely than not the application of a series capacitor would be useful to a circuit that already has some shunt capacitors on it. The response of this type of circuit to load changes would, therefore, be useful.

1. Method of Analysis

The effects of a series capacitor on circuit performance are usually calculated by considering it merely as a change in the impedance of the line through which the load is supplied. This same concept may be used to an advantage to accurately predict the voltage regulation of a circuit that utilizes shunt capacitors or a combination of series and shunt capacitors. Referring to figure 11, the single-line diagram of a feeder with a series capacitor, a shunt capacitor, and a load that may be connected, is seen. As far as the load is concerned, its current is supplied through an equivalent impedance, the characteristics of which are determined by the series and shunt capacitors, and the actual line impedance. In circuit analysis this equivalent impedance is called the *driving point* impedance[7] as viewed from the load. In the case of a single shunt capacitor bank, located on the receiving end of a line, the equivalent line impedance is merely the parallel value of capacitive reactance and the line impedance. This concept enables the regulation of a circuit consisting of any network of capacitors or line impedances, to be readily figured for a given load, by merely determining the driving point impedance as viewed from the load then using this *single* impedance in any standard regulation formula. The general equations defining the performance of the circuit in figure 11 employing this concept are derived in the appendices.

2. Effect on Regulation

Two different types of circuits were analyzed quantitatively with and without series and/or shunt capacitors in order that the points under discussion could be clearly illustrated.

Without Series Capacitors. The regulation of a circuit having an impedance of $0.05+j0.20$ per unit is shown in figure 1*a*. These values could represent the impedance of a circuit utilizing one of the larger sizes of wire, such as 4/0, and the substation transformers. The regulation of this circuit when delivering loads of various power factors and with different amounts of power-factor improvement is shown. For instance, full load (base kilovolt-ampere) at 0.60 power-factor uncorrected, curve *E*, figure 1, would give 0.19 per unit regulation, and if sufficient capacitive kilovolt-amperes were added in shunt to improve the power factor to 1.0, the regulation would be 0.23 per unit. The increase in regulation being due to the shunt capacitors increasing the *equivalent* impedance over the actual impedance of the line. In probably more familiar terms, the increase in regulation is due to the increment in leading current required by the capacitors when the voltage rises as the load is removed. The effect is somewhat magnified from the average case because the per-unit line reactance is high, meaning the circuit is heavily loaded, and the power factor is low.

Considering the other circuit analyzed attention is directed to figure 2*a*. The regulations of a circuit having an impedance of $0.15+j0.05$ per unit, are shown for the same loads as the case above. The regulations for full load and 0.6 power factor is 0.133 per unit while the regulation is reduced to 0.125 per unit when sufficient capacitive kilovolt-amperes is added to bring the power factor up to 1.0. In this instance the regulation was improved by the addition of shunt capacitors.

With Series Capacitors. The effect of adding a 0.20 per unit series capacitor in improving the circuit regulation is illustrated in figure 1*b*. The regulation is practically constant for any initial load power factor, regardless of the degree of improvement. The effect of the leading current of the shunt capacitor in increasing the regulation as in figure 1*a* has been eliminated, because the rise through the line reactance is entirely compensated by the drop through the series capacitor. By adding still more series capacitance, a circuit having the characteristics plotted in figure 1*c* is obtained. The characteristics of the load as well as the line dictate what value of series capacitance is used.

Again, referring to figure 2, the improvements offered by the series capacitor in the high-resistance circuit are illustrated. Very good regulations are obtained for the lower-power-factor loads, for all degrees of improvement. In fact, the addition of shunt capacitors improves the regulation by approximately 0.02 per unit for all loads of 0.8 power factor and below, when the net line reactance is made slightly negative by the series capacitor.

It should be noted that the series capacitor in *all* cases improves regulation, and the presence of shunt capacitors for improving power factor further improves the regulation when the line reactance is made slightly negative by the series capacitor. In these curves the improved power factor given by the abscissas considers only the improvement given by the shunt capacitors and not the small additional improvement given by the series capacitor.

The per-unit resistance of the line in figure 1 would be increased by three, or to 0.15, if it carried three times its present load. Thus, the circuit in figure 1 could be made to have regulations of those in figure 2 at three times the present load with the appropriate series capacitor. And this could be quite practical if the power factor was 0.8 or lower. This example merely indicates the immense possibilities the series capacitor promises in conjunction with the shunt capacitor in releasing line capacity where voltage drop is the limiting factor.

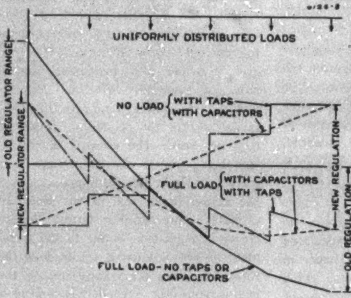

Figure 8. Voltage profile—illustrating similarity of shunt capacitors and transformer taps in facilitating voltage control

Appendix A. Voltage Regulation

The basic voltage equation for the circuit represented in figure 11*a* may be written in vector form as,

$$E_s = IZ' + E_r \qquad (1)$$

and in complex notation

$$E_s = i(\cos\Theta - j\sin\Theta)(r' + jx') + e_r \qquad (2)$$

where

E_s = sending end voltage
e_r = receiving end voltage (reference)
r' = equivalent line resistance (see appendix *B*)
x' = equivalent line reactance
Θ = power factor angle of load current referred to receiver (load) voltage
i = magnitude of load current

Solving for the magnitude of E_s there is

$$e_s = [(e_r + ir'\cos\Theta + ix'\sin\Theta)^2 + (ix'\cos\Theta - ir'\sin\Theta)^2]^{1/2}$$
$$= [e_r^2 + (iz)^2 + 2e_r i(r'\cos\Theta + x'\sin\Theta)]^{1/2} \qquad (3)$$

Voltage regulation is generally defined as the per unit rise in voltage when going from full load to no load, thus

$$R = \frac{e_s - e_r}{e_r} \qquad (4)$$

R = per unit regulation

And since normal voltage is usually that supplied at normal or full load, a simplified equation for regulation may be obtained by defining all constants in per unit on the load base. Then $e_r = 1.0 = i$ and by substituting equation 4 in 3 there is

$$R = [1 + (Z')^2 + 2(r'\cos\Theta + x'\sin\Theta)]^{1/2} - 1.0 \qquad (5)$$

This equation is plotted in figures 1 and 2 to show the effects on regulation of varying the constants of the circuit shown in figure 11*d*. Full explanation of these curves is given in the body of the paper.

Equating equation 5 to zero and solving for x', the value of equivalent line reactance (appendix *B*) is found that will give zero regulation for a given power factor.

$$R = [1 + (z')^2 + 2(r'\cos\Theta + x'\sin\Theta)]^{1/2} - 1.0 = 0 \qquad (6)$$

Solving for x' there is

$$x' = -\sin\Theta + \sqrt{1 - (\cos\Theta + r)^2} \qquad (7)$$

In the ordinary series capacitor application (figure 1*b*)

$$x' = x - x_c \qquad (8)$$

Hence for this case

$$x_c = x + \sin\Theta - \sqrt{1 - (\cos\Theta + r)^2} \qquad (9)$$

From equation 9 the per unit series capacitance can be found that will give zero regulation for any given power factor and circuit resistance within certain limits.

For instance, equating equation 7 to zero, it is found that zero regulation cannot be obtained when

$$r' > 1 - \cos\Theta \qquad (10)$$

Thus, equation 10 gives the theoretical limit of obtaining zero regulation in a circuit by using a series capacitor. This relation clearly shows that as the power factor approaches unity, the resistance must approach zero in order for zero regulation to obtain.

Conductor spacing—36-inch equivalent, circuit voltage—4 kv, capacitive kilovolt-amperes —100, length of line—one mile (100 capacitive-kilovolt-ampere miles)

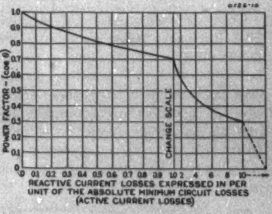

Figure 10 (right). Reactive-current copper losses

Appendix B. Equivalent Line Impedance

In appendix *A*, the term equivalent line impedance Z' is used. This is merely the driving point impedance of the circuit as viewed from the load terminals. The driv-

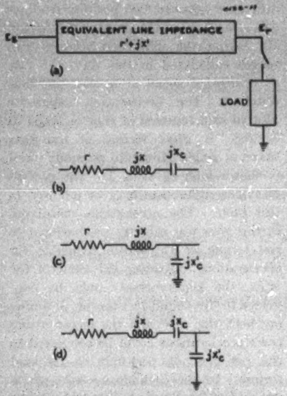

Figure 11. Schematic diagram of a load connected to its voltage source through an equivalent line impedance, which may be composed of:

(b)—Line plus series capacitor
(c)—Line plus shunt capacitor
(d)—Line plus series and shunt capacitors

ing point impedance is defined as the impedance to the flow of current when voltage is applied at the point in question with all other terminals of the network grounded.[6]

The circuit shown in figure 11*b* has an equivalent impedance of

$$Z'=r+j(x-x_c) \tag{11}$$

Thus

$$r'=r$$
$$x'=x-x_c$$

In figure 11*c* the equivalent impedance is the parallel value of the shunt capacitive reactance x_c' and the actual line impedance, thus

$$Z'=\frac{-jx_c(r+jx)}{r+j(x-x_c')}$$
$$=\frac{x_c^2r}{r^2+(x-x_c')^2}+j\frac{x_c[-x(x-x_c')-r^2]}{r^2+(x-x_c')^2} \tag{12}$$
$$=r'+jx' \tag{13}$$

where r' and x' correspond to the real and imaginary terms respectively of equation 12.

Similar expression may be deduced for any network comprising any number of voltage sources, side branches, or capacitor connections. In general network theory, the real and imaginary terms of the driving point impedance are identified as the resistance and reactance components, respectively, of the *equivalent* impedance spoken of in the body of the paper.

Appendix C. Capacitors and Power Factor

A capacitor operating at rated load represents leading kilovolt-amperes in the circuit equal to its rating. This leading kilovolt-amperes subtracted from the lagging kilovolt-amperes in the circuit results in a net value which, when combined with the kilowatts in the circuit, determines the power factor. This is true for *either* series or shunt capacitors and the relation may be shown by the vector diagram of figure 5*c*, from which the expression for the improved power factor may be derived as

$$\cos\Theta'=\frac{\cos\Theta}{[(\cos\Theta)^2+(\sin\Theta-c)^2]^{1/2}}$$
$$=\frac{\cos\Theta}{(1+c^2-2c\sin\Theta)^{1/2}} \tag{14}$$

where

$\cos\Theta$ = original power factor
$\cos\Theta'$ = improved power factor
c = per unit capacitive kilovolt-amperes in the circuit

An expression for $\cos\Theta'$, which is simpler for computing purposes is

$$\cos\Theta'=\cos\left(\tan^{-1}\frac{\sin\Theta-c}{\cos\Theta}\right) \tag{15}$$

since the answer may be read directly from a table of trigonometric functions. This relation is shown plotted in figure 7 with $\cos\Theta$ as the parameter. These curves may be used for determining the power-factor improvement effected by either shunt or series capacitors.

Appendix D. A Note on Per-Unit Constants

The principle of expressing circuit constants in per unit has been described many times in detail, hence only the equations of conversion will be given here.

Let Ω = the impedance constant in ohms. Then in per unit

$$Z=\frac{\Omega\text{ kva}}{(\text{kv})^2 1{,}000} \tag{16}$$

where

kva = base kva (arbitrary)
kv = kilovolt rating of circuit link in question

Shunt Capacitors. To express the reactance of a certain amount of shunt capacitor kilovolt-ampere in per unit, it is merely necessary to divide the base kilovolt-amperes by the capacitive kilovolt-amperes, since the capacitive reactance is equal to unity on its own base, and per-unit reactance varies directly with the base.

Thus

$$x_c'=\frac{\text{base kva}}{\text{capacitive kva}} \tag{17}$$

Series Capacitors. The per-unit reactance of a series capacitor may be obtained from equation 16 if the ohmic value is known. If the voltage across the capacitor at rated (base kva) load is e_c, then the per-unit reactance is

$$\left.\begin{array}{l} x_c=\dfrac{e_c}{e_r} \\ e_r=L-N\text{ receiver voltage} \end{array}\right\} \tag{18}$$

Or, since base current flows through the capacitor, multiplying numerator and denominator of equation 18 by the current there is obtained

$$x_c=\frac{\text{capactive kva}}{\text{base kva}} \tag{19}$$

Some Acceleration Tests on Large Synchronous Pump Motors

RAYMOND W. AGER
ASSOCIATE AIEE

ACCELERATION tests on motors may yield very interesting and valuable information. These tests show the behavior of the motor in that region between zero speed and full speed through which each motor must pass every time it is started. The usual tests do not cover this range. In fact, it is difficult or impossible to obtain the actual motor characteristics in this range on many motors by any other means. The accelerating characteristics of a motor determine the margin by which that motor is able to start and bring its load up to speed in a reasonable length of time under the least favorable conditions which might be encountered. Acceleration tests may also be used in checking theories of operation, correctness of design constants, the presence of any peculiarities in the performance curves, and, in the case of induction and synchronous machines, any tendency to lock in at a subsynchronous speed. Where the motor has been installed and connected to the load, the characteristics of the load will affect the curves obtained. Tests made under these conditions may be of special value, since they represent operating practice.

The main tests reported in this paper were made on the large synchronous pump motors used on the Metropolitan Water District[1,2] aqueduct which is to supply Colorado River water to southern California. These motors include the largest machines of this type ever built and represent the latest designs produced by three leading American manufacturers. The tests were performed in the field, after the motors had been installed, with the pumps connected, and with normal operating conditions existing. Preliminary tests were performed on small laboratory motors in order to check the test methods and equipment. Some of the results obtained in these preliminary tests are included in this paper.

Methods

The methods of test and analysis used in these experiments were similar to those described in a previous paper by the author.[3] One important change in equipment was made. In the tests reported in the present paper, stroboscopic observations were used. This change permitted the tests to be performed even at 100 per cent of rated voltage instead of the very low voltages used in the previous work.

Briefly the test procedure and equipment may be described as follows. An accurately calibrated scale was attached to the motor shaft so that the angular position of the rotor could be determined to a small fraction of a degree. This scale was illuminated by light pulses from the mercury-vapor lamp of a stroboscope, flashing 60 times per second, and a photographic record of the position of the scale was obtained. The camera was made for use with a cathode-ray oscillograph, and had a high-speed lens but no shutter. Thirty-five-millimeter motion-picture film was moved past this lens at a uniform speed by a small motor. The light pulses were of such short duration that sharp pictures were obtained even though both the film and the scale photographed were moving. In this way 60 records of rotor position were obtained each second of the test. Small calibrated disks driven by synchronous motors were photographed simultaneously for the purpose of checking the test equipment.

The records thus obtained were analyzed by numerical differentiation. The original readings gave rotor position as a function of time. Since the intervals of time between flashes were uniform, the difference between two position readings was a measure of the speed of the motor. By taking the difference between two speeds calculated in this way, the rate of change of speed or acceleration was obtained. The acceleration could be plotted as a function of time or speed as desired. A short section of the data taken at Eagle Mountain pumping plant is shown later in table I. The process of taking differences may be followed in this table. The acceleration calculated in this way was directly proportional to the torque of the motor available for acceleration. Knowing the value of the WR^2, the accelerations could be converted to the pound-feet torque, or knowing both the WR^2 and the motor rating these accelerations could be converted to the per cent or per unit of full-load torque. In the preliminary tests where the motors were tested without load, the acceleration was proportional to the motor torque minus only the small friction and windage loss torques. In the main tests where the motors were tested with the loads connected, the acceleration was proportional to the motor torque minus the friction, windage, and load torques.

An analysis of this type is possible only if certain requirements have been met. The stroboscope must produce light pulses at exactly equal time intervals or corrections for inequalities must be applied. A timing disk having 360 divisions and driven by a four-pole synchronous motor will permit timing errors of $^{1}/_{1,000}$ part of a cycle to be detected providing that disk is read to 0.1 division. In this work timing errors were corrected only where those errors were greater than twice this value. Several runs were made in which no corrections of this type were required. The determination of the timing error may be complicated by the hunting of the timing-disk motor. Hunting will occur on the starting of the main motor if the timing disk and main motors are connected to the same supply lines. Where these motors were supplied from separate transformer banks in the preliminary tests, no hunting was found.

The calibration marks on the scale of the main motor must accurately show the position of the rotor. Inaccuracies may be found to be due to the improper centering of this scale on the motor shaft or due to flexibility between the rotor and the scale. Both of these conditions were found to exist in certain of the preliminary tests. In one set of tests the center of the calibrations on the 24-inch-diameter disk used and the center of ro-

Paper 40-120, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted April 4, 1940; made available for preprinting July 10, 1940.

RAYMOND W. AGER is associate professor of electrical engineering, Cornell University, Ithaca, N. Y.; he was formerly assistant professor of electrical engineering, University of California, Berkeley.

The writer wishes to thank James M. Gaylord, chief electrical engineer of the Metropolitan Water District, for permitting these tests to be made. Also thanks are extended to those other men of the district, especially the operating staffs of the plants, for their help in the performance of the tests. The writer wishes to call particular attention to the part played by C. N. Williamson, a senior student in electrical engineering at the University of California. Mr. Williamson worked with the writer both during the preliminary tests when the method was being developed, and also when these methods were applied to the large pump motors. He has spent many hours helping in the performance, calculation, and analysis of these tests.

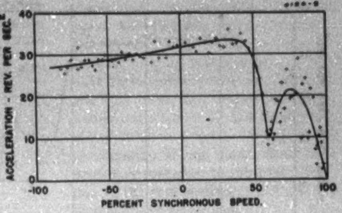

Figure 2 (right). Acceleration-speed curve of same wound-rotor induction motor with 0.75 ohm resistance added to one rotor phase

80 per cent of rated voltage applied

tation were found to be 0.03 inch apart. It was necessary to correct for this error if the best results were desired. The sudden application of power to the test motor was found to set up torsional vibrations in the motor shaft. The period of these oscillations was found to conform to the natural period of the rotor mass, the mass of the large disk, and the resilience of the connecting shaft. No correction for this effect was necessary in the tests reported, but the need for rigid connections was definitely shown.

Preliminary Tests

Two motors were used in the preliminary tests. One was a 5-horsepower wound-rotor induction motor, and the other was a 15-horsepower synchronous motor. Both machines were six pole, 60 cycle, three phase. The induction motor was tested with the rotor circuits short-circuited, and with resistance added to one rotor phase. Adding resistance to only one of the rotor phases produced the desired results of adding a cusp to the speed-torque curve. The presence of the cusp was desired since these preliminary tests were made to check the equipment, and, the more complicated the speed-torque curve, the greater the faith in the tests, providing the results of duplicate tests could be made to check. The synchronous motor was also tested under two conditions. The first tests were made with the field circuit open. The second tests were made with the field circuit short-circuited. A large bakelite disk with 500 graduations accurately engraved around the rim was mounted on the shaft of the test motor, and served as the scale giving rotor position. This disk was the only load on the test motors. The windage load of the disk was quite small, but the inertia of the disk was comparable with that of the rotor of the induction motor tested.

Power for these tests was taken from the lines of the Pacific Gas and Electric Company through transformer banks having more than ample capacity. The fluctuations in the voltage caused by the starting of these motors ranged from about three to six per cent. Voltages of 60, 80, and 100 per cent of rated value were used. The motors were first started in the reverse direction and run for several minutes until the bearings were warm. The timing motor and the stroboscope were next started. When everything was running smoothly, the main motor was reversed and the film drive motor started by the operation of a three-pole, double-throw switch. The test motor stopped, reversed, and came up to full speed in from one to three seconds.

The first run on the induction motor was made with the rotor circuit short-circuited and with full voltage applied to the stator. Following this test, runs were made with a resistance of 0.75 ohm added to one phase of the rotor circuit of the same motor. A scattering of the calculated points appeared in these tests. This scattering appeared in every run made under these conditions, and although one test might show that at a certain speed the torque was high, a second test under identical conditions might show the torque low at that same speed. The scattering was noted to be extremely bad as the motor approached synchronous speed. Vibration was suspected, but the same erratic behavior was found even after the motor had been bolted down to a heavy bed plate. Then it was observed that the indicated torques followed cyclic pulsations having a frequency equal to twice slip frequency. The unsymmetrical electric circuit of the rotor did not permit the flux to move along the rotor face with uniform resistance. Curves were drawn showing the torque as a function of time and, from these, mean values were found. These mean values checked on successive runs. The speed-torque curve of this motor, started at full voltage and with the rotor circuits short-circuited, is shown in figure 1. The speed-torque curve of the same motor, started at 80 per cent of rated voltage and with resistance added to one rotor phase, is shown in figure 2. The scattering of the points may be seen in this second figure.

The tests on the 15-horsepower synchronous motor followed closely the procedure of the induction-motor tests. The first runs were made with the field circuit open and the speed-torque curve of figure 3 was obtained. The voltage used in this test was 80 per cent of rated value. There is a small discontinuity in the curve at zero speed. This is due to the reversal of the torque due to bearing friction as the motor reversed direction of rotation. The effect was exaggerated in this motor because, being a special laboratory machine, it had the stator cradled for use as a dynamometer

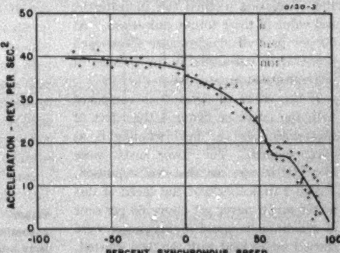

Figure 3. Acceleration-speed curve of a 15-horsepower 1,200-rpm synchronous motor

Field winding open. 80 per cent of rated voltage applied

or for the physical displacement of the stator windings relative to those of another machine on the same shaft, and therefore this motor had four sleeve-type bearings. This effect was not noted in the induction motor tests since that motor had ball bearings.

The torque pulsations were particularly pronounced when the synchronous motor was started with the field circuit short-circuited. Noise and vibration during the starting period were also found to be greater than in the previous tests. The magnitude of these torque pulsations may be seen by reference to figure 4 where the speed-torque curve is shown. The great scattering of the points above 60 per cent of synchronous speed made it impossible to draw a curve having any reasonable accuracy unless some further information was obtained. These acceleration points have been plotted to a time scale instead of speed in figure 5. The cyclic character of the pulsations is evident in this figure. The median curve may be drawn on this plot with reasonable accuracy. A second test under identical conditions gave the same median curve. Because the main scattering of the calculated points lies above 60 per cent of synchronous speed in all these tests does not signify that the torque pulsations exist only above this speed. They undoubtedly exist throughout the entire range of the test. It is only at speeds approaching synchronism that the calculation method can indicate the full value of these torque pulsations. At 50 per cent of synchronous speed each acceleration calculated is the average of one complete torque cycle.

If the curve of figure 3 is compared with the curve of figure 4 the effect of short-circuiting the field winding is at once evident. The two tests were identical except for this one condition. Figure 4 indicates that the speed of this motor might never get above 60 per cent of synchronous speed if this motor were started under load with the field shorted. In normal laboratory use this motor is directly connected to a second machine of the same design and a 20-horsepower d-c motor. With these other machines as load the motor will not come up to speed unless at least 70 per cent of rated voltage is applied to its terminals.

Tests on the Large Motors

There are three sizes of motors on the main pumps of the aqueduct system. The largest size is rated 12,500 horsepower at 450 rpm. Three of these motors are installed at Eagle Mountain pumping plant and three more are installed at Hayfield pumping plant. One of the motors at Eagle Mountain was given an acceleration test. The next motors in point of size are rated 9,000 horsepower at 400 rpm. Intake pumping plant and Gene pumping plant each have three of these motors at the present time. Two acceleration tests were made on one of the motors at Gene. A short section of the deceleration curve from full speed of this motor was obtained for the condition of a completely closed pump discharge valve. The smallest motors on the main aqueduct line are located at Iron Mountain pumping plant where each of the three motors has a rating of 4,300 horsepower at 300 rpm. An acceleration test was made on one of these motors and a deceleration test made on the same motor. The deceleration test was started with the motor fully loaded, pumping at full capacity against its normal head. All the above motors are vertical shaft, synchronous motors. They are rated at 6,900 volts, three phase, and 95 per cent power factor lead at full load.

The pump motors received their power from generators at Boulder Dam assigned to the exclusive use of the Metropolitan Water District. All the motors on this project, including the large synchronous pump motors, are started directly across the line in regular operation. Naturally, the voltage at the motor terminals could not be held constant when such large motors were started in this manner. It was known before these tests were made that the frequency also varied slightly during the starting of these large motors. The curves and calculations shown in this paper include no corrections for these variations in voltage and frequency. . The accelerations shown in the curves are those obtained under regular operating conditions.

The proper operation of the stroboscope and the timing disk demanded a source of power which was constant in voltage and in frequency. Fortunately the pumping plants had been equipped with constant-frequency sets. Each of

Figure 6. Arrangement of apparatus for main tests on the large pump motors

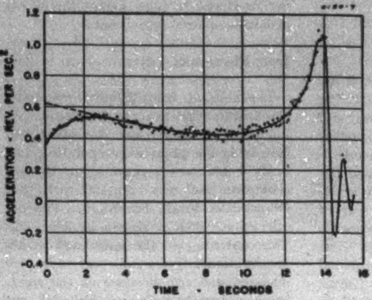

Figure 7. Acceleration-time curve of a 12,500-horsepower 450-rpm synchronous motor

Eagle Mountain pumping plant

these sets consisted of a single-phase alternator of one kilowatt capacity driven by a d-c motor from the station battery. The alternator was operated in synchronism with a temperature-controlled tuning fork. These constant-frequency sources were used in the tests. A second synchronously driven timing disk was operated from Boulder frequency. By readings taken from the two timing disks, Boulder frequency could be determined.

Because of local conditions existing at the pumping plants some modifications of the test equipment and procedure were necessary. The most difficult problem in performing the tests was in finding a method of attaching an accurately calibrated scale to the motor so that the rotor position could be determined. This problem was solved by attaching a steel tape with metric divisions around the couplings between the motors and the pumps. The couplings on the three motors tested ranged from 32.5 to 36 inches in diameter. Since the tape was calibrated in millimeters over the entire length, there were 2,593 to 2,873 divisions per revolution. Rotor position was estimated to 0.1 division. The installation of the tape proved quite simple. The coupling circumference was accurately measured with the tape. Using tape mending rivets, the tape was then riveted into a loop having a circumference about 0.3 millimeter less than that of the coupling. The tape was stretched over the coupling and remained firmly in place due to friction alone. A photograph of the equipment as it was assembled for test is shown in figure 6.

Eagle Mountain Test

The Eagle Mountain test was performed on number 1 motor with the other two motors in the plant shut down. The motor was line started according to normal operating practice, brought up to speed, and synchronized with the line using the regular automatic equipment installed in the plant. Recording was started a few seconds before the line switch was closed and was continued until after the field closing breaker had operated. The final curve of acceleration against time for this motor is shown in figure 7. All the calculated points, after the necessary corrections had been made, are indicated in this figure. The motor nearly locked into synchronism with reversed polarity. The reverse torque and the pulling into step after slipping one pole are indicated in the figure. Because of the length of time of the test only every fifth film was read. This procedure in calculation makes each calculated point the average of the conditions during five cycles. Much of the scattering of the points due to pole saliency has therefore been eliminated. During the test Boulder frequency dropped from 60.0 to 59.2 cycles.

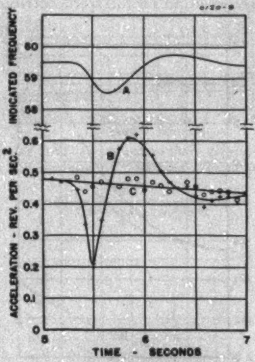

Figure 8. Enlarged section of figure 7 showing corrections

A—Curve of indicated Boulder frequency
B—Original curve drawn through test points
C—Final curve drawn through corrected test points

At three points along the curve as originally drawn there were cusps. These centered at about 7, 21, and 37 per cent of synchronous speed. After careful consideration it was found that these cusps were caused by the improper operation of the test equipment and did not represent the performance of the main motor. The data taken from the two timing disks indicated that the frequency of Boulder power had fluctuated in an altogether unexpected fashion. These fluctuations seemed much too rapid for such a system, and, it would seem from the readings, that Boulder frequency had momentarily increased due to the starting of this large motor. The only logical conclusion was that the apparent fluctuations of Boulder frequency were in reality only the hunting of the "constant frequency generator" relative to the tuning fork with which it was synchronized. The closing of the main line switch had momentarily depressed the voltage of the station battery, and this had started some hunting of the motor generator set. From theoretical considerations the correction required would be equal to:

$$\text{Correction} = -\frac{V}{60}\frac{df}{dt}$$

Where V is the velocity of the main motor in scale divisions per unit of reading time (in this case five cycles), and df/dt is the rate of change of indicated frequency per unit of reading time. With the application of these corrections, the three cusps in the acceleration curve

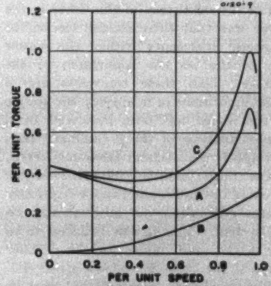

Figure 9. Speed-torque curves, Eagle Mountain

A—Accelerating torque from test
B—Hydraulic load of pump
C—Air-gap torque of motor

were entirely eliminated. Figure 8 shows the section of the original curve in the region of the largest cusp with both the original and corrected points plotted. Also shown in the figure is the curve of indicated Boulder frequency.

The left-hand end of the curve had a somewhat unexpected bend. From the electrical theory of the induction motor, the curve should follow the dotted extention instead of taking a decided downward plunge. At first this bend was thought to be due to the lack of proper lubrication of the thrust bearings of the machine. The motor had been standing idle for several hours with the entire weight of the rotor and pump on the thrust bearing. Although the bearing was immersed in oil, a proper oil film could not have existed until the motion of the rotor had swept in new oil to replace that squeezed out by the long standing.

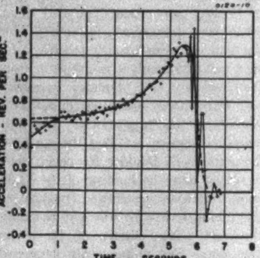

Figure 10. Acceleration-time curve of a 4,300-horsepower 300-rpm synchronous motor

Iron Mountain pumping plant

The second theory of this bend in the curve was that there existed electric or magnetic transients within the motor due to the sudden application of the voltage. That these transients are of little importance in modifying the torque of the motor has been indicated by a careful analysis of the preliminary tests and also by subsequent laboratory tests.

The third possible cause lies in the action of the automatic voltage regulators on the generators and other motors on the system. This is now believed to be one of the main causes for the peculiar shape of the curve at the low-speed end.

The accelerations calculated may be converted to per unit torques using the rating of the motor and the WR^2 values of the motor and pump. The WR^2 value has been taken from published tabulations.[4]

Unit torque is equivalent to

$$\frac{26{,}900\times \text{hp}}{N\times WR^2} \text{ revolutions per second}^2$$

where N is the synchronous speed of the motor. Since this motor had a rating of 12,500 horsepower at 450 rpm, and had a WR^2 of 506,000 pound-feet squared, unit torque corresponds to an acceleration of 1.48 revolutions per second per second. Only a part of the torque developed was used in acceleration. Part of the motor torque was used in overcoming the hydraulic load of the pump. The pump load could have been determined by making a deceleration test under identical conditions. Instead the values of motor output for full-speed operation at zero discharge were used in these calculations. The pumps at this plant require a motor output of 30.6 per cent of full load to drive them at zero discharge. For this condition the torque required varies as the square of the speed. In figure 9, curve A, is shown the data of figure 7, converted to torque and replotted using per unit speed as the abscissa instead of time. The drop off at the left-hand end of the curve has been ignored and the dotted extension used. Curve B of this figure shows the pump torque. Curve C is the sum of curves A and B and represents the air-gap torque of the motor. A curve of this type can only be obtained by a modified squirrel-cage design. The rotor bars of this motor were T shaped. This special shape and the composite structure of the bar produced to some extent the effects of double squirrel-cage design.

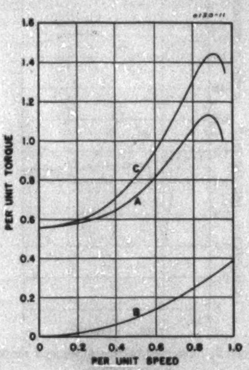

Figure 11. Speed-torque curves, Iron Mountain

A—Accelerating torque from test
B—Hydraulic load of pump
C—Air-gap torque of motor

Iron Mountain Tests

The tests at Iron Mountain pumping plant were the next to be made. At the time of these tests the other two motors in the plant were operating normally. The test procedure on the acceleration test was identical with that followed at Eagle Mountain. The acceleration curve is shown in figure 10. The scattering of the calculated points due to torque pulsations was very pronounced and can be seen at the right-hand end of the curve. Although not shown by this curve, the motor pulled into step on the reluctance torque due to salient-pole construction. It then fell out of step and slipped a pole, again locking into step with the application of the d-c field. During the starting period the frequency dropped from 59.74 to 59.46 cycles.

The same bend at the beginning end of the curve was found in this test as was found in the test at Eagle Mountain. The bend was not as pronounced however. This motor had about one-third the horsepower rating of the one at Eagle Mountain. It would therefore not effect the line as much, nor would it require as much regulator action. Also, the other two motors in this plant were operating at the time this motor was started and helped to maintain voltage. Differences in the design of the two thrust bearings may also have entered into this difference.

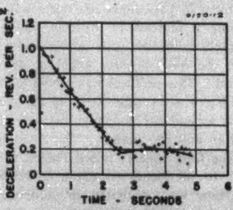

Figure 12. Deceleration-time curve of the same 4,300-horsepower synchronous motor

Motor tripped from the line while pumping under full load. Iron Mountain pumping plant

This motor had a rating of 4,300 horsepower at 300 rpm, with a WR^2 value of 339,000 pound-feet squared. The acceleration corresponding to full-load torque was 1.14 revolutions per second per second. The torque required to drive the pump at full speed with zero discharge was 0.384 per unit. The per unit accelerating torques, pump torques, and air gap torques have been plotted in figure 11. The conductors used in the pole face windings of this motor were round rods, and the curve shape obtained corresponds to that expected with this design of rotor bar.

After the motor was up to speed and was pumping water in normal fashion with the discharge valve wide open, a deceleration test was made. Upon depressing an emergency stop button the motor was immediately disconnected from the power lines, and the closing of the main discharge valve was started. The specifications on the discharge valve called for a rapid initial partial closing followed by a much slower final closing. The design accepted was to close off 95 per cent of the valve area in three seconds.[4] The deceleration curve shown in figure 12 would indicate that the high-speed part of the closing had been completed in 2.7 seconds. In these 2.7 seconds the motor had dropped to 73 per cent of synchronous speed. There was a slight rise in the decelerating torque between three and four seconds after the motor was tripped from the line. The cause of this rise is probably the surge in pipe-line pressure due to the sudden checking of the flow when this pump was shut down. Only the initial part of the deceleration test was recorded. After the pump valve had closed the deceleration was very low, and the motor and pump continued to turn for several minutes.

Gene Tests

The last motor tested was at Gene pumping plant. At the time of the tests the other two motors in the plant were shut down. Since a leakage test was in progress at one of the reservoirs, it was desired that no water should be pumped. The main discharge valve from the pump was blocked so that it could not open, and as a further precaution against an appreciable flow being pumped through the eight-inch by-pass, the motor was tripped from the line immediately after the field closing breaker had operated. Except for these modifications, the test procedure was indentical with the procedures followed in the other tests. Two acceleration tests were made. The curve obtained on the first of these tests is shown in figure 13. The field breaker closed at about 8.7 seconds and then just before 9 seconds the motor was tripped from the line. The film drive motor was also stopped at about this time and only a few readings were possible beyond this point. Some hunting of the constant-frequency set was noted and the data were corrected for this variation. The corrections were small in these tests because the hunting was not severe. The frequency dropped from 59.90 to 59.22 cycles during the starting period.

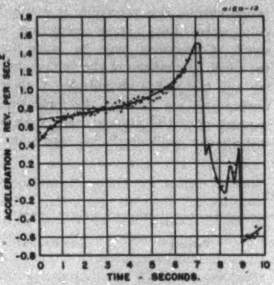

Figure 13. Acceleration-time curve of a 9,000-horsepower 400-rpm synchronous motor

Gene pumping plant

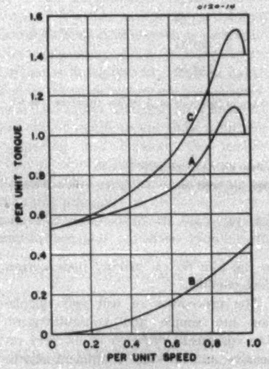

Figure 14. Speed-torque curves. Gene plant

A—Accelerating torque from test
B—Hydraulic load of pump
C—Air-gap torque of motor

The bend at the beginning of the curve was more pronounced in this test than in the test at Iron Mountain, and less pronounced than in the test at Eagle Mountain. If it were assumed that the bends were caused largely by voltage regulator action this would be the expected result. The horsepower ratings of the motors were in the same order as the prominence of the bends.

In the three tests for which the curves are reported, each motor had stood for several hours without being turned over. In the repeat test made at Gene pumping plant the motor was only allowed to remain stopped for a few seconds after coming to rest from the first test before being restarted. The starting acceleration recorded in the second test showed a small but definite increase over that recorded in the first test. This difference disappeared in about one-half second. If this difference were due to a difference in voltage conditions for the two tests, the effects should have been evident for a longer period. It has therefore been assumed that this difference in recorded accelerations was due to a change in thrust-bearing lubrication.

This motor had a rating of 9,000 horsepower at 400 rpm, and a WR^2 value of 468,000 pound-feet squared. The acceleration corresponding to full-load torque was 1.29 revolutions per second per second. The torque required to drive the pump at full speed with zero discharge was 0.45 per unit. The per unit accelerating torque, pump torque, and air-gap torque have been plotted in figure 14. The pole-face windings of this motor were similar to those of the 4,300-horsepower motor at Iron Mountain, and the curve shapes are also similar.

Further analysis of the data obtained has shown that in the main tests there was an apparent rapid fluctuation of Boulder frequency as each large motor approached synchronous speed. The motor speed at which this occurred was in each test 95 to 96 per cent of synchronous speed. There seemed to be no apparent reason for any hunting of the constant-frequency sets, and the period of this fluctuation was very much shorter than that of these sets. The natural period of the timing-disk motors was approximately one-sixth second, and this corresponded exactly to the fluctuation recorded for Boulder frequency. It seemed logical to blame this apparent fluctuation on errors of these timing disks if some cause for the starting of the hunting could be found. The torque pulsations of the main motor caused by the salient-pole construction have a period of one-sixth second for a slip of five per cent. If the torque exerted on the rotor by the stator is to vary, then the power component of the current to the stator must vary in the same way. If this varying power component is supplied through a reactive link, transmission line or transformers, then the angle between the generator voltage and the receiver voltage must vary with the power component. The result is a frequency modulation with the receiving end frequency varying above and below the generator frequency. The frequency modulation was present throughout each start. It was apparent only when resonance with the timing-disk period was approached.

Conclusions

The test methods outlined in this paper should find considerable use in the commercial and research fields. While these tests cannot replace the well-established brake and dynamometer tests for certain determinations, they may be used to obtain other data which is difficult to obtain in any other way. Any motor may be tested by this method providing a properly calibrated scale may be attached to it. Both vertical- and horizontal-shaft motors may be tested with the same equipment. There seems to be no limit to the machine size or rating.

Another advantage of this method is that the tests may be made at any voltage up to and including rated voltage. The excess heating usually present in full-voltage tests is not encountered due to the very short testing periods. A common procedure is to make a test at one voltage and then, by applying correction factors, to assume that the corrected results correspond to some other voltage. Since curves taken at different voltages do not have identical shapes due to saturation effects, this procedure is justified only where the voltage correction is small. Corrections may be made for the small fluctuations of the voltage during any test if the magnitudes of these fluctuations are known. In some subsequent tests the voltage trace from a cathode ray oscillograph has been added to the film record making these corrections possible.

Table I

Timing Disk	Boulder Disk	Rotor Position	Velocity*	Acceleration†
10.3	270.0	1,462.74		
			96.20	
190.5	81.5	1,366.54		0.86
			97.06	
10.5	252.7	1,269.48		0.88
			97.94‡	
190.5	63.9	1,458.84		0.84
			98.78	
10.4	235.5	1,360.06		0.92
			99.70	
190.5	47.3	1,260.36		0.83
			100.53	
10.5	218.7	1,447.13		0.91
			101.44	
190.6	30.4	1,345.69		0.92
			102.36	
10.5	202.2	1,243.33		

* The motor had 16 poles and the position readings were taken at intervals of 5 cycles, therefore, the 60-cycle synchronous speed of this motor was

$$287.3 \times \frac{2 \times 5}{16} = 179.56$$

† To get the acceleration in revolutions per second, these values must be multiplied by 0.50.

‡ Direct subtraction is impossible when the end of the tape has been passed during the time interval. The velocity indicated for this point is

$$287.30 + 1260.48 - 1458.84 = 97.94$$

The procedures of test and calculation are simple and straightforward. The equipment required is not very expensive, and the same equipment may be used for machines of all sizes. This equipment is not bulky, and it therefore can be easily moved should tests in remote places be desired. The time required for the making of the tests is simply that needed for the setting up and taking down of the apparatus. The actual running time is so small as to be negligible, ranging in these tests from less than one second to about 16 seconds. The photographic records must be developed, read, and calculated. This part of the work usually consumes the most time. The reading, calculating, and plotting of the data for figure 1 required between two and three hours. This was a short test of about one second running time, and no corrections were applied. Where extensive corrections must be applied due to irregularities in the operation of the test equipment, or where other factors must be considered, the time required will naturally increase.

The accuracy of the results will depend upon the accuracy with which the scale has been calibrated and read, and the extent to which the data have been corrected. Careful attention to details affecting the operation of the test, combined with accurate reading of the data from the films, produce results which need no corrections, except those due to voltage fluctuations should they be desired. The accuracy of the resulting curves from such a test should be within two per cent.

Table I is included to show the method of determination used for velocities and accelerations. The first three columns show the readings taken from the film record. The fourth column shows the calculated velocities and the fifth the calculated accelerations. The data used are from the test at Eagle Mountain pumping plant and cover the region between 8.5 and 9 seconds of that test. In the overlap of the tape used for indicating the rotor position the marking 1,210.00 centimeters was directly over 1,497.30. The tape length was therefore 287.30 centimeters.

A Generalized Equivalent Circuit in the Theory of Polyphase Commutator Motors

W. B. COULTHARD
MEMBER AIEE

THE demand for speed variation and power-factor compensation in a-c motors led to the development of the polyphase commutator types. In their simplest form these motors consist of two windings; a stator winding which is identical with that of the polyphase induction motor and a rotor winding of the closed type provided with a commutator and similar to the winding of a d-c armature. The field and armature windings are connected in series or shunt and give load characteristics similar to their d-c counterparts. Of these two characteristics the shunt is the more valuable in practice. Unfortunately this a-c motor runs at a constant speed and to secure speed variation it is necessary to inject an electromotive force onto the brushes. Variation of this electromotive force causes a change in the no-load speed. This may be shown simply by letting e_2 be the voltage induced in a rotor phase at standstill, and if e_b is the electromotive force impressed on the brushes then the rotational electromotive force e_r must be equal to the vector sum e_2+e_b. Now $e_r=K\phi n$ where n = revolutions per second, ϕ is the flux per pole and K a proportionality factor. So

$$e_r=e_2+e_b$$

or

$$n=e_2\left[1+\frac{e_b}{e_2}\right]\frac{1}{K\phi}=\frac{K_1\phi f}{K\phi}\left[1+\frac{e_b}{}\right]$$

$$\therefore n\propto f\left[1+\frac{e_b}{e_2}\right]$$

that is, by variation of e_b the speed n will be changed. This entails the use of an induction regulator to secure smooth speed variation. In the majority of practical applications this solution is uneconomical. The present-day method is to use what are termed commutator induction motors which essentially consist of an induction motor and phase converter accommodated within one machine. This type in common with other classes of a-c commutator motor is finding an ever-increasing application in practice.

The theory of these motors has of course been developed by specialists who assume prior knowledge of the subject and as the treatment lacks uniformity both as regards notation and vector representation it makes the matter difficult both to follow and correlate the performance features of the various types of field connections. This has naturally led to this class of motor not being given its due consideration.* When one compares this "single motor" treatment with that of the d-c machines, the benefits of a general theory are apparent. In the case of the d-c machine, the effect of changes in the field connections are taken care of by minor adjustments in the general theory. Of course such a theory does not deal with some details, such as commutation for example. Since all engineers are familiar with equivalent circuit in induction motor work and as analytical analysis is used rather than graphical methods, this circuit would appear to be a suitable connecting link between the various types of motor. The more so seeing that the commutator motor must operate on the same principles as the induction motor. The essentials of the theory of the transformer and induction motor with respect to the development of their equivalent circuits will now be reviewed briefly.

1. Theory of the Transformer and the Induction Motor

The performance of an air-cored transformer with a load of impedance Z on the secondary side is specified by the following vector equations:

$$V_1=Z_1I_1+j\omega MI_2$$

and

$$0=(Z_2+Z)I_2+j\omega MI_1$$

where V_1 is the applied voltage, I_1 and I_2 are the currents in the windings of impedance Z_1, Z_2 and $j\omega M$. In textbooks it is shown that the impedance from the supply side is $Z_1+\frac{\omega^2M^2}{Z_2+Z}$; whilst from the secondary side the impedance is $-\frac{j}{\omega M}[\omega^2M^2+Z_1(Z_2+Z)]$.

The introduction of an iron core, as is well known, provides two possible paths for the flux, the one through iron and the other mainly through air. The inductances of the windings may now be written as L_1+l_1 and L_2+l_2 where L denotes the inductance due to useful flux and l the inductance of the leakage flux. Thus the impedances now become

$$Z_1=R_1+j\omega l_1+j\omega L_1$$

and

$$Z_2=R_2+j\omega l_2+j\omega L_2$$

Under these conditions we have $M^2=L_1L_2$. The impedance of the transformer from the primary side is approximately

$$Z_1'=R_1+j\omega l_1+\frac{L_1}{L_2}(R_2+j\omega l_2+Z)$$

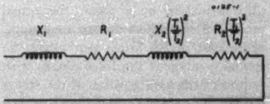
$$=\left[R_1+\left(\frac{T_1}{T_2}\right)^2R_2\right]+ j\omega\left[l_1+\left(\frac{T_1}{T_2}\right)^2l_2\right]+\left(\frac{T_1}{T_2}\right)^2Z$$

Likewise the impedance on the secondary side now approximates to,

$$Z_2'=\frac{T_2}{T_1}[R_1+j\omega l_1]+\frac{T_1}{T_2}[R_2+j\omega l_2+Z]$$

Thus both reactances are now defined solely by the leakage reactances. The approximations made involve ignoring the no-load current.

As the currents are now formulated by $I_1=V/Z_1'$ and $I_2=V/Z_2'$ respectively, the ratio of the currents is obtained as $\frac{I_1}{I_2}=\frac{T_2}{T_1}$. Inspection of the expression for the impedance Z_1' reveals that it may be imitated by two impedances connected in series as shown in figure 1 which is the equivalent circuit for the transformer. The resistance and leakage reactance of the secondary are transferred to the primary side on multiplication by $\left(\frac{T_1}{T_2}\right)^2$. This ratio is known as the transformation ratio. For our purposes this statement needs to be amplified. For the case of



X_1
R_1
$X_2\left(\frac{T_1}{T_2}\right)^2$
$R_2\left(\frac{T_1}{T_2}\right)^2$

* Since presenting the paper, the author's attention has been called to a paper by Kostenko and Sawalischin dealing with this subject. (See reference 4.)

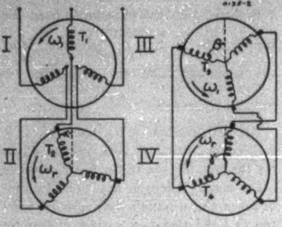

Figure 2. Diagram of connections for the generalized motor

I and III—Stator windings
II and IV—Rotor windings

the transformer it is seen that we may write

$$\left(\frac{T_1}{T_2}\right)^2=\frac{E_1}{E_2}\div\frac{I_1}{I_2}$$

or we have the transformation ratio as

$$\frac{\text{Primary induced volts}}{\text{Secondary induced volts}}\div\frac{\text{current in primary to balance secondary current}}{\text{secondary current}}$$

Passing to the case of the induction motor, some modifications are required due to rotation of the secondary. Here the secondary voltage varies with slip so that E_2 is replaced by sE_2 and the frequency of the currents and voltage in the rotor is of slip frequency. The secondary reactance is now sX_2 and the ratio is $\frac{1}{s}\left(\frac{T_1}{T_2}\right)^2$. The equivalent circuit is shown in figure 3 where the omission of the no-load current is rectified by a shunt admittance g_0-jb_0 connected across the voltage corresponding to that due to the air-gap flux.

2. Commutator Motors

Since commutator motors act on the same general principles as the induction motor, the above ideas can be applied with modifications due to certain constructional differences. In a commutator motor the position of the phases is fixed by the brush gear and as the latter is stationary the position of the rotor phases is fixed in space. Rotation of the armature merely alters the individual conductors making up a phase, the actual number of conductors therein is constant. Movement of the brush gear alters the spatial position of the rotor phases with respect to the fixed position of the stator phases. The electromotive force and current between brushes are now of supply frequency. This allows the rotor brushes to be connected to the supply and as we have seen in the case of a shunt motor allows a voltage suitable for speed variation to be impressed thereon. This should be compared with the induction motor where the phase connections rotate and the rotor phases consist of the same conductors at all times. In both cases the amplitude of the generated electromotive force will vary with slip.

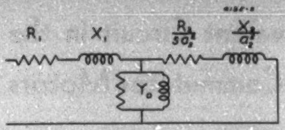

Figure 3. Equivalent circuit for an induction motor

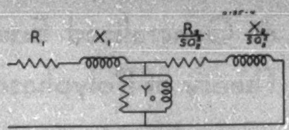

Figure 4. Equivalent circuit for motor with armature, brushes short-circuited

A further feature introduced by the commutator is that the magnetic axis of a rotor phase is fixed by the brush axis, exactly as for the d-c machine. So movement of the brush axis causes the rotor axis to move with respect to the stator axis. Since the air gap magnetomotive force is the resultant of the stator and rotor magnetomotive forces the air-gap flux will be moved by brush movement. This alters the time relationship between the induced stator and rotor electromotive forces.

In the subsequent discussion certain assumptions will be made. These are:

1. All voltages and currents are sinusoidal. In certain currents there is some deviation from the sine wave.
2. The relationship between current and flux is linear and saturation effects are neglected.
3. The reactance of the commutator winding is given by ωL; the effect of single-phase fields and the like is neglected.
4. Though all quantities are considered, some may be of minor importance in certain classes of motor. These would be detected readily when the constants of a given motor are measured.

3. Generalized Machine

A review of the possible combinations of the windings used in commutator motors leads to a general machine shown in figure 2. Here there are two windings accommodated on both the stator and the rotor. These windings are labelled I, II, III, and IV and they are connected up in pairs in series through brushes bearing on the commutators. The position of any winding may be altered without alteration to the main theory, thus allowing any machine to be discussed. For a series motor, for example, windings I and II would be used, whilst for a shunt motor, windings I and IV could be considered.

Assuming that the mesh-connected rotor is replaced by its equivalent star winding, the effective turns in each phase are T_1, T_2, T_3, and T_4. Let the angular displacement between the axes of the various windings with respect to the stator axis be α, β, and γ as shown. Then for the windings (I) and (II) carrying a current I_1 the resultant magnetomotive force per phase will be given by $\boldsymbol{A}_a=I_1[T_1+T_2\epsilon^{j\alpha}]$. Likewise in windings III and IV the resultant magnetomotive force per phase is given by $\boldsymbol{A}_b=I_2\times[T_3\epsilon^{j\beta}+T_4\epsilon^{j\gamma}]$.

The expression $\epsilon^{j\alpha}$ means that the vector I_1T_2 is advanced in space by an angle α on the vector I_1T_1. This applies to the displacement shown in figure 2. When the brushes are moved against the direction of rotation of the motor then this vector is retarded and given by $I_1T_2\epsilon^{-j\alpha}$. As the windings are mutually coupled the ampere turns must balance giving $\boldsymbol{A}_a=\boldsymbol{A}_b$, when the effect of the magnetizing ampere-turns are neglected. Or

$$\frac{I_2}{I_1}=[T_1+T_2\epsilon^{j\alpha}]\div[T_3\epsilon^{j\beta}+T_4\epsilon^{j\gamma}]$$

Denoting $\frac{T_2}{T_1}$ by a_2, $\frac{T_3}{T_1}$ by a_3 and $\frac{T_4}{T_1}$ by a_4

then

$$\frac{I_2}{I_1}=\frac{1+a_2\epsilon^{j\alpha}}{a_3\epsilon^{j\beta}+a_4\epsilon^{j\gamma}}$$

This is defined as the current ratio and is denoted by A_1.

Since the flux is assumed to be rotating counterclockwise, the brush shift shown causes the rotor electromotive force to appear later in time phase by an angle equal to the brush shift. Thus for windings I and II the resultant electromotive force $E_1=e_1+e_2\epsilon^{-j\alpha}$, where e_1 and e_2 are the electromotive forces at standstill. At any speed this may be written as

$$E_1=4.44\phi f[T_1+sT_2\epsilon^{-j\alpha}]\times10^{-8}$$

For windings III and IV the resultant electromotive force is

$$E_2=4.44\phi f[T_3\epsilon^{-j\beta}+sT_4\epsilon^{-j\gamma}]\times10^{-8}$$

Thus the voltage ratio is

$$\frac{E_1}{E_2}=\frac{1+sa_3\epsilon^{-j\alpha}}{a_3\epsilon^{-j\beta}+sa_4\epsilon^{-j\gamma}}=A_2\text{ say}$$

The complete transformation ratio is now given as $A_1\cdot A_2$. In appendix I it is shown that this expression is a complex quantity and can be written as $a+jb$. On denoting the total secondary impedance by R_2+jX_2, it is obvious on transfer to the primary side that the equivalent secondary resistance becomes R_2a-X_2b and the equivalent secondary reactance is R_2b+X_2a. Here R_2 must include the whole secondary resistance with an allowance for brush drop, whilst X_2 includes the reactance of all components of the secondary. In certain cases some of the reactances may be expressed in terms of each other.

In appendix II some examples are given in deriving the equivalent circuits for various classes of motor with shunt characteristics. In general these expressions are complicated but may be split into terms involving slip designated as the resistance and reactance of the main circuit. Others are independent of slip and may be grouped as admittances. This arrangement is arbitrary. For the case of the induction motor with frequency converter in the secondary, the main circuit resistance and reactance are given as

$$\frac{R_2}{a_3^2}\,\frac{1}{s+K\cos\gamma}$$

and

$$\frac{X_2}{a_3^2}\cdot\frac{1}{s+K\cos\gamma}$$

respectively. The no-load admittance is given as

$$(X_2-jR_2)\,\frac{a_3^2}{Z_2^2}\cdot K\sin\gamma$$

For practical purposes this may be written as

$$-j\,\frac{a^2}{R_2}K\sin\gamma=-jB$$

since X_2 is generally small. As the value of B is negative it is capacitive. This is the component of the circuit which ensures improvement of the power factor. Its action depends on the brush shift angle as shown.

4. Analysis of the Motor Performance

As for the induction motor, when the equivalent circuit is determined the analysis of motor performance proceeds by the usual methods. In appendix III an analysis of the Osnos motor is indicated. A full analysis may be found in the references given.

In general it is seen that the equivalent circuit of the motors discussed may be reduced to:

1. A shunt circuit carrying an almost constant current.

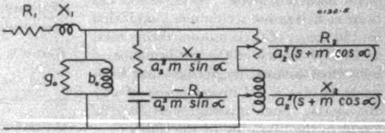

Figure 5. Equivalent circuit of a shunt motor

2. A main circuit whose components consist of a constant resistance (R_1), a constant reactance (X_1), a variable resistance (R_2), and a variable reactance (X_2).

In appendix IV the equation for such a circuit is given as

$$x^2+y^2-2Ax-2By=0$$

This is the equation of a circle provided that A and B are constants. The values of A and B are given by

$$A=\frac{V}{2X_1\left[1-\frac{R_1}{R_2}\cdot\frac{X_2}{X_1}\right]}$$

and

$$B=\frac{V}{2R_1\left[-\frac{X_1}{X_2}\cdot\frac{R_2}{R_1}\right]}$$

So the test for the locus of the current to be a circle is given by:

$$\frac{\text{Variable reactance }(X_2)}{\text{Variable resistance }(R_2)}=\text{constant for a given brush position}$$

To illustrate we will consider the induction motor with frequency converter. From appendix II we have the circuit constants as

$$R_A=\frac{r_3+r_4}{a_3^2}\cdot\frac{1}{s+K\cos\gamma}=R_2$$

and

$$X_A=\frac{sx_3+x_4}{a_3^2}\cdot\frac{1}{s+K\cos\gamma}=\frac{x_3}{a_3^2}+\frac{x_4-x_3K\cos\gamma}{a_3^2(s+K\cos\gamma)}$$

Hence

$$X_2=\frac{x_4-x_3K\cos\gamma}{a_3^2(s+K\cos\gamma)}$$

Hence

$$\frac{X_2}{R_2}=\frac{x_4-x_3K\cos\gamma}{r_3+r_4}=\text{a constant for any given brush angle}$$

Again for the Osnos motor the value of the ratio becomes approximately

$$\frac{X_2}{R_2}=-\frac{XK\cos\beta}{R_2}$$

which is also independent of slip. Thus the locus of the current is a circle. It is to be noted that there is a circle for each brush position. In appendix III it is demonstrated that for the Osnos motor the locus of the centers of the circles is an ellipse. The center of this ellipse corresponds to the center of the equivalent induction motor. For the Schräge motor for any fixed value of β the locus of the centers is a line parallel to the applied voltage axis. If in this motor the brush gear may be rotated as a whole then for each brush angle β the loci of the centers are lines parallel to the voltage axis. In actual tests it is found that the major axis of the ellipse does not lie on the x axis but at a small angle thereto. The question of construction of load, and torque lines has not yet been considered.

Conclusion

A general equivalent circuit for commutator motors has been developed. The constants of this circuit are based on a determination of the transformation ratio from the expressions for the magnetomotive force and voltage. For this class of motor, where the voltage vector equation method entails a consideration of time and space phase relationships, this method has the advantage that these are obtained from a preliminary consideration of the relative positions of the windings. Throughout subsequent analytical work all quantities are in their correct phase relationship to each other.

In common with other machines once the equivalent circuit has been developed, the performance of the motor is obtained by standard methods as used in the case of the induction motor. As the object has been to determine a common foundation for the theory of these motors, rather than a detailed theory of the performance of individual motors, no attempt has been made to give a full investigation of any one motor. Such investigations may be found in the literature of the subject.

List of Symbols

A_1 = current ratio = (secondary current)/primary current = I_2/I_1.
A_2 = voltage ratio = (primary voltage)/secondary voltage = E_1/E_2
B, b = susceptance of equivalent circuit
E_1 = electromotive force induced in primary phase windings
E_2 = electromotive force induced in secondary phase windings
f = supply frequency
G, g = conductance of equivalent circuit

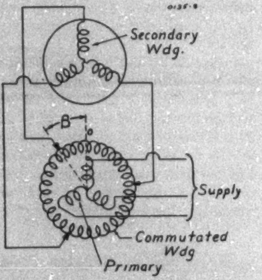

Figure 8. Diagram of connections of the Osnos-type motor

(In the case of the Schräge motor the star point is opened and the ends of the secondary windings terminated in brushes bearing on the commutator)

K = a ratio; for three winding motors = a_3/a_4
m = K/a_2 for shunt motor; for Osnos motor = $K \cos \beta$
n = $K \sin \beta$ (Osnos)
n_0 = synchronous speed
Q = α/π (Schräge motor)
R_1 = total resistance of primary windings per phase
R_2 = total resistance of other windings per phase; if there is a commutator, the resistance must include an allowance for the brush resistance (R_A). R_2 is a variable resistance
$r_1r_2r_3r_4$ = resistances per phase reduced to equivalent star values.
s = slip
T = effective turns per phase, that is, actual turns times the winding factor. All windings reduced to an equivalent star winding. The subscripts denote the actual member
V = applied voltage
X_1X_2 = total leakage reactances of primary and other circuits. X_2 variable
$x_1x_2x_3x_4$ = leakage reactances per phase at supply frequency
α, β, γ = space angles of windings (figure 2)
ϕ = flux

Appendix I

Determination of the Transformation Ratio (A)

The transformation ratio is

$$\frac{\text{Primary induced voltage}}{\text{Secondary induced voltage}} \times \frac{\text{secondary current}}{\text{primary current to balance the secondary current}}$$

Here it is

$$\frac{1+sa_2\epsilon^{-j\alpha}}{a_3\epsilon^{-j\beta}+sa_4\epsilon^{-j\gamma}} \times \frac{1+a_2\epsilon^{j\alpha}}{a_3\epsilon^{j\beta}+a_4\epsilon^{j\gamma}}$$

On rationalizing this becomes:

$$\frac{(1+a_2\epsilon^{j\alpha})(1+sa_2\epsilon^{-j\alpha})(a_3\epsilon^{j\beta}+sa_4\epsilon^{j\gamma})(a_3\epsilon^{-j\beta}+a_4\epsilon^{-j\gamma})}{(a_3^2+2a_3a_4 \cos (\gamma-\beta)+a_4^2)(a_3^2+2sa_3a_4 \cos (\gamma-\beta)+s^2a_4^2)} =$$

$$\frac{[1+sa_2^2+a_2(\epsilon^{j\alpha}+s\epsilon^{-j\alpha})][a_3^2+sa_4^2+a_3a_4(s\epsilon^{j(\gamma-\beta)}+\epsilon^{-j(\gamma-\beta)})]}{[a_3^2+2a_3a_4 \cos (\gamma-\beta)+a_4^2][a_3^2+2sa_3a_4 \cos (\gamma-\beta)+s^2a_4^2]}$$

For a three-winding type motor, winding II is omitted, that is, $T_2=0$ and so $a_2=0$. Making this substitution the ratio now becomes:

$$\frac{a_3^2+sa_4^2+a_3a_4(s\epsilon^{j(\gamma-\beta)}+\epsilon^{-j(\gamma-\beta)})}{(a_3^2+2a_3a_4 \cos (\gamma-\beta)+a_4^2)(a_3^2+2sa_3a_4 \cos (\gamma-\beta)+s^2a_4^2)}$$

With a secondary resistance of the form R_2+jX_2, the value of the equivalent resistance is given by:

$$R=r_1+\frac{R_2[a_3^2+sa_4^2+a_3a_4(1+s) \cos (\gamma-\beta)]+X_2a_3a_4(1-s) \sin (\gamma-\beta)}{[a_3^2+2a_3a_4 \cos (\gamma-\beta)+a_4^2]\cdot[a_3^2+2sa_3a_4 \cos (\gamma-\beta)+s^2a_4^2]}$$

and the equivalent reactance is:

$$X=x_1+\frac{X_2[a_3^2+sa_4^2+a_3a_4(1+s) \cos (\gamma-\beta)]-R_2a_3a_4(1-s) \sin (\gamma-\beta)}{[a_3^2+2a_3a_4 \cos (\gamma-\beta)+a_4^2][a_3^2+2sa_3a_4 \cos (\gamma-\beta)+s^2a_4^2]}$$

For this class of motor, let the arrangement of the windings be as shown in figure 8, then R_2 is the total resistance of the secondary winding, that is, the resistances of windings T_3 and T_4 plus an allowance for the contact resistance of the brushes. Since this latter depends on the current in the brushes, an average value will be used to simplify calculations. Also X_2 is the total leakage reactance of these windings comprising x_3 the reactance of the commutated winding T_3 and sx_4 the reactance of T_4. The frequency of the currents in this latter circuit is of slip frequency.

As the windings T_1 and T_3 are located in the same slots the two windings are mutually coupled and so x_3 may be expressed in terms of x_1. The coefficient of coupling will of

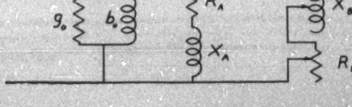

Figure 9. The equivalent circuit of the Osnos motor

Figure 10. The simplified diagram of connections of the Osnos motor

course depend on the dimensions of the slot. Here in the interest of simplicity this coefficient is taken as unity.

The mutual flux linking both windings is due to the resultant ampere-turns of these two windings and may be expressed as $I_1T_1-T_2T_3\epsilon^{j\beta}$. Hence the reactive drop in the primary due to the presence of the tertiary winding becomes

$$x_1I_1[1-a_3I_3\epsilon^{j\beta}/I_1]$$

The last term gives the alteration due to the mutual effect of the current in the commutated winding. The voltage drop is thus given by

$$V_1=I_1\left[Z_1-jx_{13}\frac{a_3}{a_3+a_4\epsilon^{-j\beta}}\right]$$

where x_{13} represents the mutual effect. On expansion we obtain the impedance as

$$Z_1'=\left[r_1-x_{13}\frac{a_3a_4\sin\beta}{a_3^2+2a_3a_4\cos\beta+a_4^2}\right]+ j\left[x_1-x_{13}\frac{a_3(a_3+a_4\cos\beta)}{a_3^2+2a_3a_4\cos\beta+a_4^2}\right]$$

This gives the effective resistance and reactance of the primary winding. In practice it is found that $x_{13}a_3a_4\sin\beta$ is very small and so may be neglected. Also x_{13} is almost equal to x_1. Thus we approximate as

$$R_1\cong r_1$$

and

$$X\cong\frac{x_1}{1+K\cos\beta}$$

For the commutated winding the effective ampere-turns are likewise reduced by

$$-\frac{I_1T_1}{I_3T_3}\epsilon^{-j\beta}$$

so the voltage equation becomes

$$V_3=I_3\left[Z_3-j\frac{x_{31}}{a_3}(a_4\epsilon^{-j\beta}+a_3)\right]$$

The impedance of that winding is now given by

$$Z_3'=\left[r_3+x_{31}\frac{\sin\beta}{K}\right]+ j[x_3-x_{31}(1+1/K\cos\beta)]$$

$$Z_3'\cong\left[r_3+x_3\frac{\sin\beta}{K}\right]-j\left[x_3\frac{\cos\beta}{K}\right]$$

Appendix II

Determination of Equivalent Circuits for Motors With Shunt Characteristics

(a). INDUCTION MOTOR

The windings requisite are I and IV without brush gear. Thus the frequency in the rotor circuit is of slip frequency, and we obtain:

$$A_1=\frac{I_4}{I_1}=\frac{T_1}{T_4}$$

and

$$A_2=\frac{E_1}{E_2}=\frac{T_1}{sT_4}.$$

giving a transformation ratio of $\frac{1}{sa^2}$. The equivalent circuit is shown in figure 3.

(b). A POLYPHASE MOTOR WITH ARMATURE, THE BRUSHES SHORT-CIRCUITED

The frequency in the rotor circuit is now of supply frequency. Using windings (1) and (2) with the stator connection removed we have:

$$A_1=\frac{I_2}{I_1}=\frac{T_1}{T_2\epsilon^{j\alpha}}$$

and

$$A_2=\frac{E_1}{E_2}=\frac{T_1}{sT_2\epsilon^{-j\alpha}}$$

So

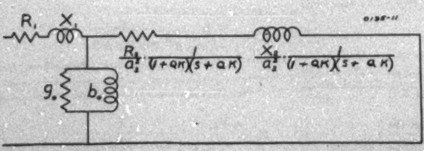
$$A=\frac{1}{sa^2}$$

The equivalent resistance and leakage reactance are now given by

$$\left[r_1+\frac{R_2}{sa^2}\right] \text{ and } \left[x_1+\frac{X_2}{sa^2}\right]$$

respectively.

The equivalent circuit is now as shown in figure 4. For this motor there is no improvement in power factor due to brush shift.



R_1
X_1
$\frac{R_2}{a_2^2}\cdot\frac{1}{(1+aK)(s+aK)}$
$\frac{X_2}{a_2^2}\cdot\frac{1}{(1+aK)(s+aK)}$
g_0
b_0

Figure 11. The equivalent circuit of the Schräge motor arranged for speed change only

(c). SHUNT MOTOR

For a simple shunt motor with its armature connected to the supply through a variable-ratio transformer, the electromotive force impressed on the brushes will be KV or approximately KE_1. Thus with windings I and II, the series connection being eliminated, the current ratio is

$$\frac{I_2}{I_1}=\frac{1}{a_2\epsilon^{j\alpha}}$$

The standstill voltage in the rotor

$$e_2=e_1\frac{T_2}{T_1}=e_1a_2$$

The voltage ratio is

$$\frac{E_1}{E_2}=\frac{e_1}{e_1[K+sa_2\epsilon^{-j\alpha}]}$$

Thus the complete ratio becomes

$$\frac{1}{a_2^2(s+m\epsilon^{j\alpha}}$$

where $m=\frac{K}{a_2}$

The referred secondary impedance is

$$\frac{R_2+jX_2}{a_2^2(s+m\epsilon^{j\alpha})}$$

Rationalizing and by the methods of the next section this becomes

$$R_A=\frac{R_2}{a_2^2}\cdot\frac{1}{s+m\cos\alpha}$$

and

$$X_A=\frac{X_2}{a_2^2}\cdot\frac{1}{s+m\cos\alpha}$$

$$R_B=\frac{X_2}{a_2^2}\cdot\frac{1}{m\sin\alpha}$$

and

$$X_B=-\frac{R_2}{a_2^2}\cdot\frac{1}{m\sin\alpha}$$

The equivalent circuit is shown in figure 5. It will be noted that this circuit does not show the total supply current drawn by the motor but only that taken through the stator.

(d). INDUCTION MOTOR WITH FREQUENCY CONVERTER

This arrangement uses two separate machines, an induction motor which is windings I and III and a rotary phase advancer which would be winding IV. The voltage generated in the phase advancer is due to the flux set up by its own current.

We will assume that this voltage is given by $e_4=Ke_3\epsilon^{j\gamma}$ where K is a constant. The total voltage in the whole secondary circuit is now given as $se_3+Ke_3\epsilon^{j\gamma}=e_2$ say where e_3 is the standstill voltage in the rotor circuit. So

$$\frac{E_1}{E_3}=\frac{e_1}{e_3(s+K\epsilon^{j\gamma})}=\frac{1}{a_3(s+K\epsilon^{j\gamma})}$$

The current ratio is given by

$$\frac{I_3}{I_1}=\frac{T_1}{T_3}=\frac{1}{a_3}$$

Hence the transformation ratio is

$$\frac{1}{a_3^2(s+Ke^{j\gamma})}$$

The referred secondary impedance

$$Z_2'=\frac{R_3+jX_3}{a_3^2(s+Ke^{j\gamma})}$$

where $R_3=r_3+r_4$ and $X_2=sx_3+x_4$, and r_4 and x_4 are the resistance and reactance of the phase-advancer armature. Rationalizing the equivalent impedance becomes

$$Z_2'=\frac{R_2^2}{a_3^2}(1+\tan^2\phi)\frac{1}{[R_3(s+K\cos\gamma)+X_3K\sin\gamma]-j[X_2(s+K\cos\gamma)-R_3K\sin\gamma]}$$

where

$$\tan\phi=\frac{X_3}{R_2}$$

This expression gives Z_2' in the form $\dfrac{1}{G-jB}$

where

$$G=\frac{a_3^2\cos^2\phi}{R_2^2}[R_3(s+K\cos\gamma)+X.K\sin\gamma]$$

and

$$B=\frac{a_3^2\cos^2\phi}{R_2^2}[X_2(s+K\cos\gamma)-R_3K\sin\gamma]$$

These expressions may be further split into $G=G_A+G_B$ and $B=B_A+B_B$. By usual methods, the corresponding resistances and reactances are:

$$R_A=\frac{r_3+r_4}{a_3^2}\,\frac{1}{s+K\cos\gamma}$$

and

$$X_A=\frac{sx_3+x_4}{a_3^2}\,\frac{1}{s+K\cos\gamma}$$

and

$$R_B=\frac{sx_3+x_4}{a_3^2}\cdot\frac{1}{K\sin\gamma}$$

and

$$X_B=-\frac{r_3+r_4}{a_3^2}\,\frac{1}{K\sin\gamma}$$

The equivalent circuit now consists of three parallel circuits as shown in figure 6. Alternatively the last terms may be left as a conductance and a susceptance and connected in parallel across the no-load branch. In practice it is found that R_B is small and may be omitted. The circuit now becomes that shown in figure 7. The phase advancing feature is clearly shown as the condensive susceptance $-\dfrac{a_3^2K\sin\gamma}{r_3+r_4}$.

(e). THE THREE-WINDING MOTORS

This type includes such well-known motors as the Osnos, Schräge, Torda, etc. For the Osnos motor the diagram of connections is shown in figure 8. The primary winding is carried on the rotor and in the same slots is the lap winding. The secondary winding is carried on the stator. This machine may be simulated by using windings I, III, and IV. Winding III is the lap winding.

The voltage induced in the lap winding is now given by

$$e_3=e_1\frac{T_3}{T_1}\epsilon^{-j\beta}$$

The voltage ratio now becomes

$$\frac{E_1}{E_2}=\frac{e_1}{e_1(sa_4+a_3\epsilon^{-j\beta})}=\frac{1}{a_4(s+K\epsilon^{-j\beta})}$$

The current ratio is now given as

$$\frac{1}{a_4(1+K\epsilon^{j\beta})}$$

and the transformation ratio as

$$\frac{1}{a_4^2(1+K\epsilon^{j\beta})(s+K\epsilon^{-j\beta})}$$

The referred secondary impedance is now given as

$$Z_2'=\frac{R_2+jX_2}{a_4^2(1+K\epsilon^{j\beta})(s+K\epsilon^{-j\beta})}$$

Using the values of R_2 and X_2 as given in appendix I we have

$$Z_2'=\frac{(R_2+x_3\sin\beta/K)+j(sx_4-x_3\cos\beta/K)}{a_4^2(1+K\epsilon^{j\beta})(s+K\epsilon^{-j\beta})}$$

$$=\frac{jx_4}{a_4^2(1+K\epsilon^{j\beta})}+\frac{(R_2+x_3\sin\beta/K)-j(Kx_4\epsilon^{-j\beta}+x_3\cos\beta/K)}{a_4^2(1+K\epsilon^{j\beta})(s+K\epsilon^{-j\beta})}$$

The numerator of the second term on expansion becomes

$$\left(R_2+\frac{x_3}{K}\sin\beta-Kx_4\cos\beta\right)-j\left(Kx_4\cos\beta+\frac{x_3}{K}\cos\beta\right)$$

This we will denote by $R+jX$. The second term of the expression for Z_2' may be written as,

$$Z_2''=\frac{R^2\sec^2\phi}{a_4^2}\left[\frac{1}{\{R(s+K^2+(1+s)K\cos\beta)+(s-1)XK\sin\beta\}-j\{X(s+K^2+(1+s)K\cos\beta)-(s-1)RK\sin\beta\}}\right.$$

where $\tan\phi=\dfrac{X}{R}$

We may thus segregate into terms dependent on slip and terms independent thereon and so obtain:

$$R_A=\frac{R(K+\cos\beta)-X\sin\beta}{a_4^2K(1+2K\cos\beta+K^2)}$$

and

$$X_A=\frac{X(K+\cos\beta)+R\sin\beta}{a_4^2K(1+2K\cos\beta+K^2)}$$

$$R_B=\frac{R(1+K\cos\beta)+XK\sin\beta}{a_4^2s(1+2K\cos\beta+K^2)}$$

and

$$X_B=\frac{X(1+K\cos\beta)-RK\sin\beta}{a_4^2s(1+2K\cos\beta+K^2)}$$

The equivalent circuit is now shown in figure 9 where R and X have values as above.

Alternatively we may group the terms as:

$$R_A=\frac{R(s+K^2+sK\cos\beta+K\cos\beta)+sXK\sin\beta}{a_4^2[(s+K^2+sK\cos\beta+K\cos\beta)^2+s^2K^2\sin^2\beta]}$$

$$X_A=\frac{X(s+K^2+sK\cos\beta+K\cos\beta)-sRK\sin\beta}{a_4^2[(s+K^2+sK\cos\beta+K\cos\beta)^2+s^2K^2\sin^2\beta]}$$

and

$$R_B=-\frac{X}{K\sin\beta}\quad\text{and}\quad X_B=\frac{R}{K\sin\beta}$$

As further analytical development is difficult we will make certain simplifying assumptions.

Since $sK\sin\beta$ is small we will neglect terms involving that quantity. Then we have

$$R_A=\frac{R_2}{a_4^2}\,\frac{1}{(s+K^2+sK\cos\beta+K\cos\beta)}\cong\frac{R_2}{a_4^2}\,\frac{1}{(s+K\cos\beta)(1+K\cos\beta)}$$

and

$$X_A\cong\frac{X}{a_4^2}\,\frac{1}{(s+K\cos\beta)(1+K\cos\beta)}$$

The term R_B is also negligibly small and so we have

$$R_B=0\quad\text{and}\quad X_B\cong\frac{R_2}{K\sin\beta}$$

Or in terms of susceptance we have

$$-B=\frac{K\sin\beta}{R_2}$$

This branch will be connected across the short circuit representing the variation of the no-load susceptance due to brush shift and as it is capacitive it will improve the power factor of the motor.

The parameters of the main circuit are approximately:

$$R_1\cong r_1$$

$$X_1=\frac{x_1}{1+K\cos\beta}+\frac{x_4/a_4^2}{1+K\cos\beta}=\frac{X}{1+K\cos\beta}\ \text{say}$$

$$R_2=\frac{r_3+r_4}{a_4^2}\cdot\frac{1}{(s+K\cos\beta)(1+K\cos\beta)}$$

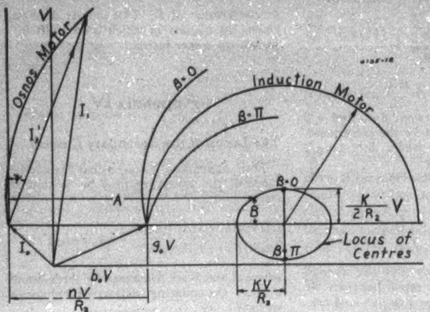


Figure 12. Circle diagram for the Osnos motor

$$X_2=-\frac{\left(x_1+\frac{x_4}{a_4^2}\right)K\cos\beta}{(s+K\cos\beta)(1+K\cos\beta)}$$

$$=-\frac{XK\cos\beta}{(s+K\cos\beta)(1+K\cos\beta)}$$

Substitution of $m=K\cos\beta$ and $n=K\sin\beta$ reduce the above expression to those shown in figure 10. This figure corresponds to the simplified circuit given by Rudra.

(f). Schräge Motor

This motor is identical in arrangement to the Osnos motor excepting that the phases of the secondary winding (4) are not connected in star but each end of a winding is terminated by brushes. Both sets of the brushes are arranged to rotate by means of a handwheel and worm gear. A variable voltage is taken off the commutator and is injected into the secondary winding. Unless arrangements are made to rotate the brush gear as a whole, the power factor of the motor is not compensated.

Let the brushes of a phase be separated by an angle of 2α, then the number of conductors between brushes will be given by $\alpha/\pi T_3=QT_3$ say. If e_3 is the diametric electromotive force of the lap winding then the electromotive force due to the lap winding is given by Qe_3. The resistance of this winding will be specified by Qr_4 and the reactance by Q^2x_4.

Assuming that the axes of all windings coincide with that of the stator winding, then the electromotive force of the whole secondary circuit is given by

$$se_4+Qe_3=e_4(s+KQ)$$

where

$$K=a_3/a_4$$

The voltage ratio now becomes

$$\frac{e_1}{e_4(s+KQ)}=\frac{1}{a_4(s+KQ)}$$

The current ratio is

$$\frac{1}{a_4(1+KQ)}$$

The transformation ratio now becomes

$$\frac{1}{a_4^2(1+KQ)(s+KQ)}$$

The equivalent resistance and reactance of the motor now becomes

$$R_e=r_1+\frac{R_2}{a_4^2}\cdot\frac{1}{(1+KQ)(s+KQ)}$$

and

$$X_e=x_1+\frac{X_2}{a_4^2}\,\frac{1}{(1+KQ)(s+KQ)}$$

Here

$$R_2=r_4+Qr_3+r_\Delta \text{ and } X_2=sx_4+Q^2x_3$$

where r_Δ is a term to account for the drop at the brush contacts. The equivalent circuit for the motor is shown in figure 11.

As for the Osnos motor we may express x_3 in terms of x_1. On substituting $\beta=0$ in the expression obtained for the Osnos motor we get $r_1=r_1$, $x_1=\frac{x_1}{1+KQ}$, $r_3=r_3$, and $x_3=-x_1a_3a_4/Q$. There is no change in the value of the equivalent resistance R_e as given above but the equivalent reactance now becomes,

$$X_e=\frac{x_1}{1+KQ}+\frac{sx_4-x_{13}a_3a_4Q}{a_4^2(1+KQ)(s+KQ)}$$

$$X_e=\frac{x_1+x_4/a_4^2}{1+KQ}-\frac{x_{13}a_3a_4Q+x_4KQ}{a_4^2(1+KQ)(s+KQ)}$$

$$=\frac{X}{1+KQ}-\frac{Qa_3a_4X}{a_4^2(1+KQ)(s+KQ)}$$

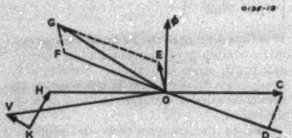

Figure 13. Vector diagram for the induction motor

$OH=E_1$
$KH=IX_1$
$VK=IR_1$
$OV=V=$ applied volts

Appendix III

Analysis of the Performance of a Motor

When the parameters of the equivalent circuit are known, the analysis of the performance of a motor proceeds along the well-known lines of that of an induction motor as given in many textbooks. To illustrate we take the case of the Schräge motor. Since there is no compensation of power factor and the no-load current is almost the same for all brush positions we will neglect the no-load current.

Thus the input per phase of the motor is given by $VI\cos\phi=I_1^2R_e$. Substituting for R_e we have the input as

$$I_1^2\left[R_1+\frac{R_2}{a_4^2(1+KQ)(s+KQ)}\right]$$

The stator loss is given as $I_1^2R_1$ and the rotor copper loss as $I_2^2R_2$; on subtracting these the output per phase of the motor is obtained as

$$I_2^2\left[\frac{1-s}{s+KQ}\right]R_2$$

The torque in watts is given by

$$\frac{1}{2\pi n_0}\cdot\frac{I_2^2R_2}{S+KQ}$$

where n_0 is the synchronous speed. The starting torque is given by

$$\frac{1}{2\pi n_0}\cdot\frac{I_2^2R_2}{1+KQ}$$

The power factor of the motor is given by

$$\cos\left[\tan^{-1}\frac{X_1+X_2/\Delta}{R_1+R_2/\Delta}\right]$$

where

$$\Delta=a_4^2(1+KQ)(s+KQ)$$

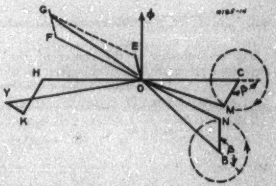

Figure 14. Simplified vector diagram for the Osnos motor

$CM=K\times$ electromotive force in commutator winding
$OM=$ resultant secondary electromotive force $=Z_2'$
$NB=KI_2$
$ON=I_2+KI_2=$ primary value of $I_2=-OF$

When both sets of brushes are on the same commutator segment, that is, $Q=0$ the motor is a simple induction motor. On substitution of $Q=0$ in the above expressions it is seen that they reduce to those of the induction motor.

The co-ordinates of the center of the circle diagram are given as

$$X_c=\frac{V}{2X}\,\frac{R_2'(1+KQ)}{R_2'+R_1QK(1+KQ)}$$

and

$$Y_c=\frac{V}{2}\cdot\frac{KQ(1+KQ)}{R_2'+R_1QK(1+KQ)}$$

The radius is

$$\frac{VR_2'(1+KQ)}{2[R_2'+R_1QK(1+QK)]}\left[\frac{1}{X_2^2}+\left(\frac{KQ}{R_2}\right)^2\right]^{1/2}$$

where

$$R_2'=R_2/a_4^2$$

On substitution $KQ=-p$ these results check with those given by Arnold.

Writing

$$\tan\theta=\frac{Y_c}{X_c}=KQ\frac{X}{R_2'}=-p\frac{X}{R_2'}$$

it is seen that for negative values of p the center of the circle is below that for the induction motor ($p=0$) whilst for positive values the center is above.

For the Osnos motor the motor performance may be analyzed in a similar fashion. Neglecting the no-load input and using the simplified equivalent circuit (figure 10) the input per phase is $I_1^2R_e$. Subtracting the losses due to the stator resistance, the input to the rotor is obtained as

$$I_2^2(1+m)^2\frac{R_2}{a_4^2(1+m)(s+m)}=I_2^2\frac{R_2}{a_4^2}\cdot\frac{1+m}{s+m}$$

Subtracting the losses in the rotor we have the input watts as $I_2^2\frac{R_2}{a_4^2}\cdot\frac{1+m}{s+m}$.

The torque in watts is

$$\frac{I_2^2}{2\pi n_0}\,\frac{R_2}{a_4^2}\cdot\frac{1}{s+K\cos\beta}$$

whilst the starting torque is

$$\frac{I_2^2}{2\pi n_0}\cdot\frac{R_2}{a_4^2}\cdot\frac{1}{1+K\cos\beta}$$

The co-ordinates of the center of the circle for a given brush angle are given by

$$X_c=\frac{V}{2X}\cdot\frac{1+m}{1+\frac{R_1}{R_2'}m(1+m)}$$

and

$$Y_c=\frac{V}{2R_2}\cdot\frac{m(1+m)}{1+\frac{R_1}{R_2'}m(1+m)}$$

To simplify these expressions we assume the design is such that the equivalent rotor resistance is equal to that of the primary as for the case in an induction motor. That is, $R_2'=R_1(1+m)$

So

$$X_c=\frac{V}{2X}\quad\text{and}\quad Y_c=\frac{V}{2R_2}m$$

For this motor $\tan\theta=\frac{mX}{R_2}$ and when m is positive, that is, between $\beta=0$ and $\pi/2$ the center is above that for the corresponding induction motor, whilst for $\beta=\pi/2$ to π the center is below.

In this motor the no-load current is given by

$$I_0=V\left[g_0-j\left(b_0-\frac{K\sin\beta}{R_2}\right)\right]$$

This expression shows that the no-load current varies with the brush position. It is seen that with $\beta=0$ or π the no-load current reduces to that of the induction motor namely $V(g_0-jb_0)$. Further when $\sin\beta=b_0R_2'/K$ the no-load current is at its minimum value and is in time phase with the applied voltage. For the usual machine constants this value of β is about 30 degrees or 150 degrees. For a value of β between these two limits the no-load current is leading. Thus the locus of the no-load current with a variable β is a line at right angles to the voltage axis and at a distance Vg_0 from the origin.

The locus of the centers of the approximate circles may be derived as follows:

At $\beta=0$ or $\beta=\pi$ as noted above the no-load currents are identical but Y_c now varies. At $\beta=0$, $Y_c=VK/2R_2'$ whilst at $\beta=\pi$, $Y_{c\pi}=-VK/2R_2'$. Thus the distance between these two centers is VK/R_2'. At $\beta=\pi/2$ and $\beta=3\pi/2$, Y_c is now zero for both brush positions. For all brush angles, X_c is a constant and is measured from the end of the no-load current vector. Here it is seen that the no-load currents differ by $2VK/R_2'$. So the distance between these two centers is $2VK/R_2'$. At any angle it is seen that the co-ordinates of the center measured from the center of the equivalent induction motor are given by

$x=VK\ \sin\beta/R_2'$ and
$y=VK\ \cos\beta/2R_2'$.

Thus it is seen that the locus of centers gives an ellipse where axes are VK/R_2' and $VK/2R_2'$ respectively. This is shown in figure 12.

It is of interest to compare the vector diagram of the polyphase induction motor with that of the three-winding Osnos motor. On the diagrams shown all quantities are given in terms of the primary or for a ratio of 1:1. In order to obtain the true values in any circuit the vector must be multiplied by the appropriate transformation factor. Thus in figure 13 representing the diagram for the induction motor the true value of the secondary current $=T_1/T_4$ times the value shown, the true value of the secondary electromotive force $=T_4/T_1$ times vector and the true value of the resistance is $(T_4/T_1)^2$ times the value shown on the diagram.

In figure 14 is shown a simplified vector diagram for the Osnos motor. Here MC is the electromotive force in the commutated winding referred to the primary side. The position of this vector is varied with brush position. Also BN represents the current in the lap winding and $OB+BN=ON=$ primary value of I. This simple diagram shows the manner in which brush shift improves the power factor.

Appendix IV

The Locus of the Secondary Current

From appendix I it is seen that the admittance of the secondary may be written in the form

$$\frac{(A_0+jA_0')+s(A_1+jA_1')}{(B_0+jB_0')+s(B_1+jB_1')}=x+jy\ \text{(say)}$$

where A and B are constants for given brush angles. On equating reals and imaginaries we have

$$s(B_1x-B_1'y-A_1)+B_0x-B_0'y-A_0=0$$

and

$$s(B_1y+B_1'x-A_1')+B_0y+B_0'x-A_0'=0$$

Eliminating the variable s, we have

$$(B_1x-B_1'y-A_1)(B_0y+B_0'x-A_0')-(B_0x-B_0'y-A_0)(B_1y+B_1'x-A_1')=0$$

or

$$x^2+y^2-x\left[\frac{A_1B_0'+A_0'B_1-B_0A_1'-A_0B_1'}{B_1B_0'-B_0B_1'}\right]+y\left[\frac{A_0'B_1'-A_1B_0-B_0'A_1'+A_0B_1}{B_1B_0'-B_0B_1'}\right]+\frac{A_1A_0'-A_0A_1'}{B_1B_0'-B_0B_1'}=0$$

This is the equation of a circle with center at

$$X_c=\frac{A_1B_0'+A_0'B_1-B_0A_1'-A_0B_1'}{B_1B_0'-B_0B_1'}$$

$$Y_c=\frac{A_1B_0-A_0'B_1'+B_0'A_1'-A_0B_1}{B_1B_0'-B_0B_1'}$$

The radius is given by

$$\left[\frac{A_1A_0'-A_0A_1'}{B_1B_0'-B_0B_1'}\right]^{1/2}$$

It is thus seen that the locus of the current under conditions of constant applied voltage and brush angle is a circle. Varying the brush angle causes a shift in the position of the centers and a variation in the length of the radius.

Due to the complications we adopt a method given by Rudra and Walker. In figure 12 let x, y be the co-ordinates of P such that $OP=I=$the load component of the primary current.

$\theta=$the angle between I and V the impressed electromotive force
$G=$the conductance of the main circuit
$B=$the susceptance thereof

Then

$$VB=I\sin\theta=x$$

and

$$VG=I\cos\theta=y$$

But the reactance $= \frac{B}{B^2+G^2} = \frac{V^2B}{V^2B^2+V^2G^2}$

$$= \frac{xV}{x^2+y^2}$$

Likewise the resistance is $= \frac{yV}{x^2+y^2}$

Now the resistance and reactance of the general equivalent circuit may be written as R_1+R_2 and X_1+X_2 where R_1, X_1 are constant terms belonging to the primary and R_2, X_2 are variable terms of the secondary circuit.

Thus

$$\frac{xV}{x^2+y^2} = X_1+X_2$$

and

$$\frac{yV}{x^2+y^2} = R_1+R_2$$

or

$$\frac{xV-(x^2+y^2)X_1}{x^2+y^2} = X_2$$

and

$$\frac{yV-(x^2+y^2)R_1}{x^2+y^2} = R_2$$

$$\therefore \frac{yV-(x^2+y^2)R_1}{xV-(x^2+y^2)X_1} = \frac{R_2}{X_2}$$

This becomes, after some work,

$$(x^2+y^2) - y\frac{VX_2}{X_2R_1-X_1R_2} + x\frac{VR_2}{X_1R_2-R_1X_2} = 0$$

or

$$x^2+y^2-2By-2Ax=0$$

This is the equation for a circle, provided that A and B are constant. The center of the circle is given by $X_c = A$ and $Y_c = B$ and the radius by $\sqrt{A^2+B^2}$.

Braking Magnets for Watt-Hour Meters

I. F. KINNARD
MEMBER AIEE

J. H. GOSS
ASSOCIATE AIEE

THE function of a braking magnet for a watt-hour meter is to produce a retarding torque acting to balance the electromagnetic driving torque. This retarding torque must be strictly proportional to the velocity of the disk for the watt-hour meter to register accurately. This is readily seen from a consideration of the fundamental watt-hour meter equation.[1]

This is probably the most exacting application for a permanent magnet due not only to the squared relationship between the flux[1,2] and braking torque but also the fact that watt-hour meters are the cash registers for the gigantic electrical industry. They are expected to operate accurately under all conditions indoors and outdoors for periods of five to ten years without servicing.

It is the purpose of this article to discuss suitable test methods for determining characteristics of permanent magnets and to review actual test data that have been obtained on magnets of various types and materials. A careful investigation is outlined showing the relationship of coercive force and the ability of the magnet to withstand demagnetizing fields. An attempt is made to formulate the requirements of an ideal watt-hour meter braking magnet and to illustrate how a designer might make a logical choice from materials that are now available.

A relatively small number of permanent magnet materials have been actually used for braking magnets for watt-hour meters. During the past ten years a number of new and interesting permanent magnet materials have been developed and made commercially available. Table I shows a list of some of these materials which includes both those that have been used and those that might conceivably be used at the present time.

Test Methods

Extreme accuracy of test is needed in determining braking magnet performance for reasons referred to above. As watt-hour meters are installed for service periods ranging from five to ten years, the magnet must remain constant within narrow limits over these periods if the watt-hour meter is to retain its initial calibration. Change in meter magnet strength as a function of time is referred to as aging of the magnet. Such aging may be either positive or negative, depending upon the shape of the magnet, the magnetic material, and its condition of stabilization. It is highly desirable to accurately determine aging trends in order to minimize the time required to judge aging characteristics. Furthermore, as will be shown later, in some magnetic materials aging is extremely small. It is, therefore, essential to develop testing methods that are accurate to within a few hundredths of one per cent. The obtaining of such accuracy is obviously outside the range of ordinary magnetic measurements.

Several methods[2] have been used for determining the permanency of braking magnets. These may be classified as follows:

1. Watt-Hour Meter Method

This method consists of placing magnets in actual watt-hour meters and observing the change of registration as a function of time. It has been shown that unless this method is carried out with extreme care, it is subject to variations

of several tenths of one per cent, which definitely limits its usefulness.[3]

2. Standard Fluxmeter Method

A standard magnetic method of measuring the total flux of a magnet consists of employing the well-known arrangement of a search coil and a flux-measuring galvanometer. Inaccuracies of two to five per cent are to be expected when using this method, and even under the most carefully controlled conditions, an inaccuracy in the order of one per cent is still to be expected. This method of test measurement was used in obtaining data shown in this article only in connection with the tests on bar magnets. In this study relatively large changes in flux were being measured and a more precise method was not necessary.

3. Precision Flux Test Method

Figure 1 shows an arrangement for measuring the total air-gap flux of a braking magnet. This arrangement has a precision of 0.02 per cent; that is, the readings on a given magnet can be repeated to within this limit. The absolute value of the total flux of the magnet is not, of course, known to anything like this precision. The object of this test is to detect changes and not to measure absolute values so that it is sufficient to measure and record changes from the initial measurement.

In operation the magnet to be measured is placed in a locating fixture and a search coil is dropped under the action of gravity through the magnet air-gap. At the instant the search coil cuts the flux in the magnet gap, the coil assembly actuates a switch which reverses a direct current flowing in the primary of the mutual inductance.

The voltage induced in the secondary

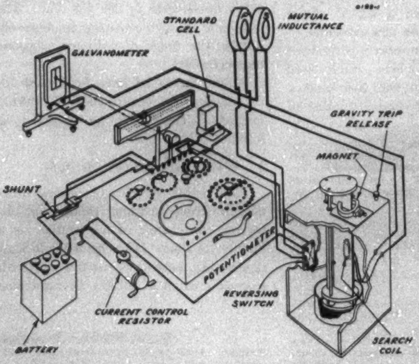

Figure 1. Precision flux-measuring equipment for permanent magnets

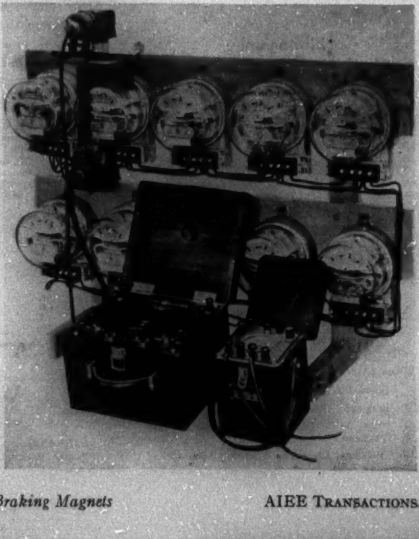

Figure 2 (right). Precision watt-hour meter equipment for measuring the permanency of braking magnets of the mutual inductance opposes the voltage induced in the search coil. A flux galvanometer is in series with the search coil and the secondary of the inductance. If the direct current flowing in the primary of the mutual inductance is adjusted to the correct value, the galvanometer will not deflect thereby indicating a true balance. The direct current is accurately measured with the potentiometer, and this evaluates the flux of the permanent magnet. All data shown on flux measurements were obtained using this method with the exception of those on bar magnets.

4. Precision Watt-Hour Meter Method

The total flux of a permanent magnet is not necessarily an accurate indication of the permanency of the magnet from the standpoint of its ability to produce braking torque. It is conceivable that a redistribution of the total flux over the pole face of the magnet might occur. It is also necessary to measure over-all braking strengths in determining the constancy of the complete magnet assembly. Figure 2 shows a refinement of method number 1 which has a precision within 0.03 per cent based on using the average of a group of ten magnets. This method differs fundamentally from method number 1 in that the human error is eliminated by the use of a photoelectric control and a reference standard of high accuracy is employed to which the portable standard watt-hour meter is compared.[3] This method of test was employed in obtaining data on all actual braking strengths of magnets.

Test Results

For many years the standard material used in the United States for watt-hour meter braking magnets has been chromium steel (material number 2, table I). Stabilizing processes have been developed which make these magnets very permanent, and they have given a high degree of satisfaction in service. It is of interest to study some of the facts that have been learned from operating experience, and research on chromium steel as they present an excellent background against which to judge and analyze new materials for this application.

1. Aging Phenomena

For the purpose of discussion in this paper certain terms are used which for a clear understanding should be definitely defined. The term, "aging" is applied to any change in the total flux or magnetic braking strength of a permanent magnet over a period of time.

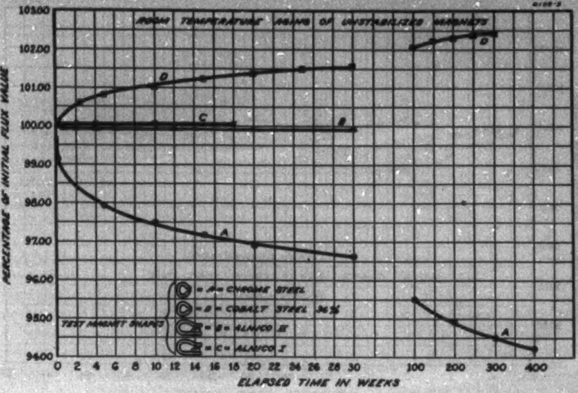

Figure 3. Room-temperature aging of unstabilized magnets

For the purpose of analysis, aging may be divided into two classifications:

(*a*). *Metallurgical Aging.* Applied to changes in total flux or braking strength with time due to metallurgical changes in the material.

(*b*). *Magnetic Aging.* Applied to changes in total flux or braking strength with time due to the magnetic state of the magnet excluding metallurgical changes.

It is also convenient in discussing aging to speak of "natural aging" and "artificial aging."

(*a*). *Natural Aging.* Any changes resulting over a period of time without any severe or unfavorable artificial conditions being present.

(*b*). *Artificial Aging.* Any changes resulting from the application of severe artificial conditions such as extremes in temperature.

Treatments that are given magnets to control aging are referred to as "stabilizing treatments." As used in this discussion, stabilization may be defined as:

Stabilization. The term, "stabilization" refers to certain treatments to reduce or eliminate subsequent aging of magnets.

In figure 3 are shown the aging characteristics of unstabilized magnets made from chromium steel, cobalt steel, and two types of Alnico.

Metallurgical Aging. The aging characteristics shown are largely due to the degree of metallurgical stability of the material, and it is quite obvious that in the case of curves *A* and *D* some form of stabilizing treatment is needed. A large amount of work involving heat treatments at various temperatures and varying lengths of time has shown that for the commonly used chromium steel a low temperature anneal is very effective in eliminating metallurgical aging provided the temperature and time are carefully controlled.

For chromium steel this stabilization treatment has been carried out on magnets both before and after magnetization and careful checks by the precision flux testing method have shown conclusively that the effect is independent of the magnetization of the magnet and must, therefore, be entirely metallurgical in nature.

Curve *D* indicates that unstabilized cobalt magnets tend to increase in flux with time. This phenomenon has not been further investigated since there has been no application of cobalt steel in

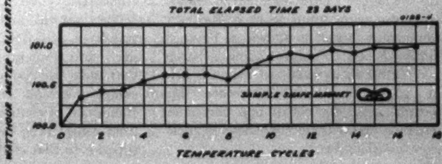

Figure 4. Cyclic aging of unstabilized Alnico II magnets

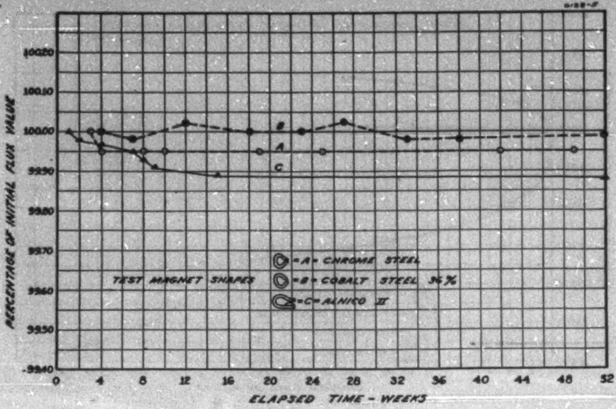

Figure 5. Room-temperature aging of stabilized magnets

watt-hour meter magnets in this country.

Magnetic Aging. In chromium steel magnets magnetic aging is a much smaller factor than is metallurgical aging. A suitable stabilizing treatment for chromium steel to practically eliminate magnetic aging has been found to be a temperature cycle, after the magnet has been fully magnetized and demagnetized an appropriate amount, that will take the magnet well above and below any temperature to which it will be subsequently subjected. As a result of such a temperature cycle, the magnet flux may change as much as 0.75 per cent. If the magnet is given a second and a third temperature cycle identical with the first, slight additional changes in the flux will be noted, although the first cycle produces almost the complete change. This stabilizing effect is entirely destroyed if the magnet is demagnetized after the temperature cycle and must be repeated if stability against temperature cycles is to be again obtained. This clearly indicates that this is a matter of magnetic aging and not metallurgical aging.

This clean-cut distinction between the two forms of aging does not necessarily exist with all forms of magnetic materials. In the newer materials such as Alnico, magnetic aging seems to be of the most importance, since as shown in figure 3, curves *B* and *C*, natural aging is barely perceptible in unstabilized magnets held at a constant ambient temperature. The natural aging for cobalt and chromium magnets under these conditions is, however, considerable.

Careful tests, however, under conditions of varying temperatures indicate that Alnico does require very careful stabilization treatments. This is shown by figure 4 which is the cyclic temperature aging of unstabilized magnets made from Alnico II.

Figure 5 shows the natural aging under constant temperature (22 degrees centigrade) of a group of stabilized magnets of chromium steel, cobalt steel, and Alnico, similar to those shown in figure 3. Figure 6 shows the cyclic temperature aging of stabilized chromium steel and Alnico II.

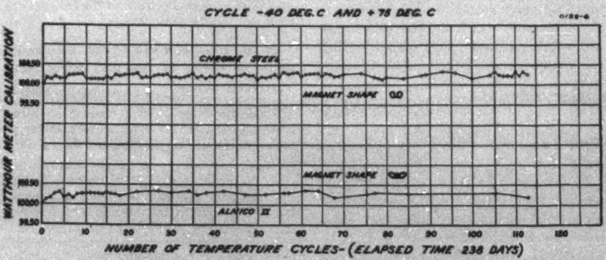

Figure 6. Cyclic temperature aging of stabilized magnets

The natural and artificial aging of stabilized Alnico II magnets and stabilized chromium magnets show definitely that these two types of magnets are fully comparable and satisfactory from the standpoint of continued stability. Stabilized Alnico II is also shown to be much superior to that of the unstabilized magnets shown by figure 4 when subjected to cyclic temperature aging.

It is of importance to note that the present practice in the United States of mounting watt-hour meters out-of-doors makes doubly important cyclic temperature stability. This installation practice has developed very largely within the past ten years. Prior to this watt-hour meters were mounted in protected or semi-protected locations.

2. Miscellaneous Conditions

Several points are of particular interest in regard to their effect on aging:

(*a*). If a magnet assembly of two chromium steel magnets is made up of one strong magnet and one weak magnet, it is of interest to note that the assembly is practically as stable as when two magnets of equal strength are paired.

(*b*). The normal method of demagnetizing a magnet from the fully magnetized state is to subject it to a demagnetizing field supplied by a coil of wire large in diameter in comparison to the size of the magnet. The magnet is placed approximately in the center of the coil and an a-c current is raised from "0" to a maximum and returned to "0." This same effect can, of course, be obtained by holding the current in the coil always at the maximum value but by moving the magnet from a distance into the center of the coil and out again. The direction of application of the demagnetizing field with respect to the magnet is important. Figure 7 shows that if the direction of the field is normal to plane of the magnet and parallel to the watt-hour meter disk, the magnet will show approximately one-sixth of the magnetic aging that will occur if the field is applied in the plane of the magnet and normal to the disk.

(*c*). In service braking magnets may be subjected to demagnetizing fields resulting from transient surges produced by switching or lightning currents flowing in the coils of the watt-hour meter or in adjacent leads. If a magnet is partially demagnetized by a high speed surge, such as would result from lightning, it is of interest to note whether or not the stability of the magnet is affected. Figure 8 shows the results of measurements made on chromium steel and Alnico II braking magnets when subjected to certain surges and then checked by the precision watt-hour meter method. It will be seen that the magnets are comparatively stable after this treatment.

Effect of External Fields

The degree of demagnetization of a braking magnet resulting from a given switching surge or lightning discharge through the watt-hour meter coils or in adjacent conductors is important. This is largely a matter of the fundamental properties of the permanent magnet material. It should be kept in mind in considering the effect of external fields that whether or not a magnet should withstand such fields is closely tied in with installation practice, particularly the location of adjacent conductors which may carry heavy currents or transient surges.

In carrying out a series of measurements to evaluate the relationship between fundamental magnetic properties and the effect of external fields, it was desirable to work with magnetic shapes that were simple. For this reason bar magnets were chosen. Their dimensions and other pertinent data are shown in table II.

All of the bar magnets were fully magnetized and then placed in a Helmholtz coil arrangement with the bar magnet placed lengthwise on the centerline of the coil system midway between the coils. The size of the coils and the number of turns used were always the same for both coils but were varied for the direct current, 60-cycle and fast surge conditions.

Use was made of the method of design devised by K. L. Scott[4] in choosing the dimensions of the bar magnets. The sintered oxide magnet sample was longer than this method of design indicated it should be. The samples of chromium steel, Alnico, and cobalt steel were, however, more nearly in accord with Scott's method. It should be recognized that the data obtained with these bar magnets are not directly applicable to watt-hour meter braking magnets quantitatively, although they are representative qualitatively.

In arriving at the values of demagnetizing force for each of the wave shapes employed, it should be noted that the maximum value of the wave was used.

Figures 9 and 10 show that the demagnetization of the test magnet by either a d-c field or a 60-cycle field is a function of the coercive force of the material. It is of interest to note the permanent magnet materials of widely different compositions fall on smooth curves relating coercive force as determined from a d-c demagnetization curve, and the percentage of the original flux remaining following the application of a demagnetizing field of given strength.

Table II

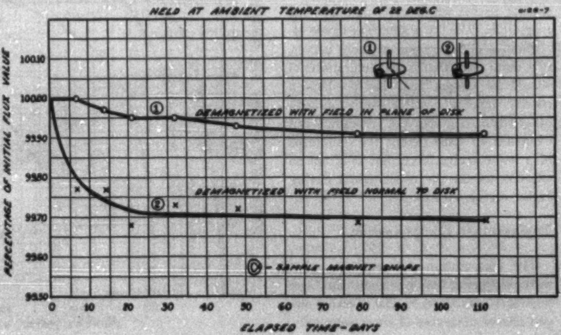
Material	3% (Min) Chromium Steel	36% Cobalt Steel	Alnico II	Sintered Oxide
Cross section (cms²)	1.85	1.62	2.84	1.32
Length (cms)	22.1	12.9	5.2	6.2
B_r (residual induc.)	9,200	10,000	7,200	2,100
H_c (coercive force)	68	210	540	860
Maximum B	13,050	17,300	12,400	5,300
Maximum permeability	92.5	37.8	9.6	
Specific resistance microhms/cm/cm sq.	43.7	73.9	59.7	225×10^6
Density lbs/cu in	0.270	0.294	0.255	0.097
Rockwell hardness	C-60	C-62	C-53	

Figure 11 shows the effect of surges that are very much faster and compare in nature with those resulting from fields of lightning discharge currents. A 15–45 microsecond surge means that the time from initiation of the surge to the crest value of the surge was 15 microseconds and the time from initiation to half value on the tail of the wave was 45 microseconds. A number of surges of different values were used in this work.

A fourth material is shown on this curve which is nonmetallic in nature and as shown in table I is composed of oxides of iron and cobalt. The electrical resistance of this material as shown in table II is extremely high as compared to the other magnetic materials. Differing as this material does in composition, it is seen that it falls on smooth curves relating coercive force and percentage of initial flux remaining after the application of a demagnetizing surge of a given peak value.

In dealing with surges of high speed, it is possible to achieve a measure of protection by encasing the magnet in a protective coating of a highly conductive material, for example, copper. With the simple bar magnet where it is practical to encase the entire magnet, this shielding is quite effective and comes about due to the eddy currents induced in this highly conducting coating. The shielding serves to limit the penetration of the demagnetizing field. Figure 11, curve *A*, shows the gain made by completely encasing the chromium steel bar magnet sample in a two-mil coating of copper. It will be noted that the points on the chromium steel curve are effectively moved up the curve by the copper plate responding as would a material of higher coercive force. It should be noted, of course, that this protective coating would give added surge protection to the other materials even those of high coercive force such as Alnico and sintered oxide. This protection in practice is not necessary except for low coercive force materials such as chromium steel. For very heavy demagnetizing fields, this coating appears to be more effective than for fields of lower intensity. This shielding in actual practice is reduced in effectiveness due to the inability to build up a protective coating of sufficient thickness in exposed air gaps of the magnet.

Figure 7. Effect of demagnetization with the field applied in different directions for chromium-steel watt-hour meter magnets



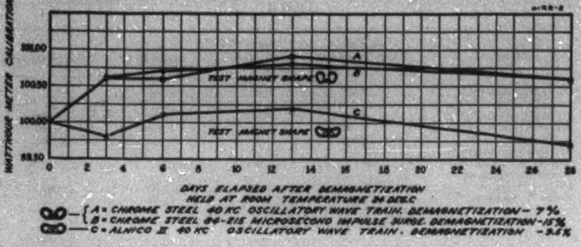


Figure 8. Stability of watt-hour meter magnets following surge demagnetization

Figure 12 shows an interesting effect that is of importance in arriving at the actual degree of demagnetization resulting from a surge. It is seen that repeated surges of like shape and crest value produce increasingly greater demagnetizing effects. This repeated surge effect has some connection with the conductivity of the magnet material as has been borne out by test results on the sintered oxide material. Due to the high electrical resistance of this material as shown by table II, it has very little self-shielding under surge conditions so that the initial surge produces practically the same effect as would be produced by an infinite number of surges of the same magnitude. This is not the case with chromium steel which is successfully demagnetized by a measurable amount up to 14 surges. The results in figure 11 are based on a single surge of the magnitude shown, whereas figure 13 takes into account the accumulative surge effect and is based on the ultimate demagnetization after 15 surges. It will be noted that figure 13 has been plotted for but one wave shape (15–45 microseconds). The relation between coercive force and percentage of original flux remaining still falls on smooth curves which differ in shape and magnitude from those shown in figure 11.

From a consideration of these curves, it is quite clear that a magnetic material should be chosen that has as high a coercive force as possible consistent with other required properties. Shielding can overcome to some extent the handicaps of a low coercive force, but it is not so effective as the use of materials having higher coercive forces.

Temperature Compensation

The temperature compensation of a watt-hour meter braking magnet has been previously described.[5] The effective air-gap flux of a magnet changes with temperature, and as has been pointed out, the change in flux is reflected in the accuracy of registration of the watt-hour meter. Other errors which are usually small in magnitude may be present in a given watt-hour meter, and it may be convenient to compensate the braking magnet to correct for these changes also. Figure 14 shows the results of ambient temperature variation on a modern single-phase watt-hour meter with an uncompensated chromium steel magnet, an uncompensated Alnico II magnet, a compensated chromium steel magnet and a compensated Alnico II magnet. It will be noted that the meter registration with the uncompensated chromium steel magnet and the uncompensated Alnico magnet is practically the same indicating that both materials have the same temperature coefficient.

Temperature compensation of braking magnets is very important for watt-hour meters installed outside of buildings. The errors that would result without compensation as shown by figure 14 may easily reach 2.5 per cent.

Specifications

From the foregoing it is evident that the designer has many problems to consider in selecting the materials and in the actual design of a watt-hour meter braking magnet. It has been found useful to formulate the following specifications in organizing the available data and arriving at the best possible design

1. Stability

The magnet should be stable under conditions of:

(*a*). Normal temperature operation

(*b*). Cyclic temperature operation over the range service conditions impose

(*c*). Stray fields, direct current or alternating current, of the magnitudes they will be subjected to ranging from commercial frequencies to lightning surges

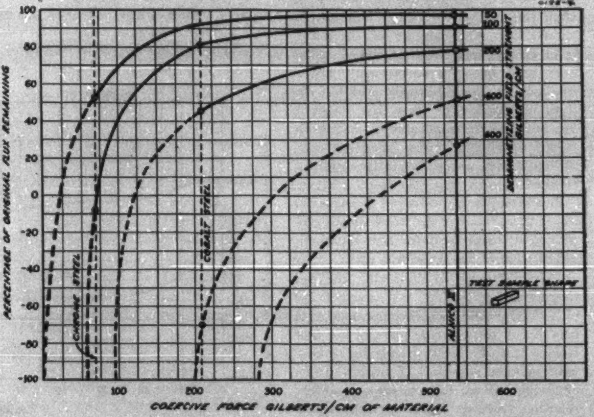
2. Compensation

The magnet must maintain constant braking irrespective of temperature change over the range of operating temperatures. If desirable this compensation may be increased to allow for errors in other parts of the meter.

3. Adjustments

The magnet should be provided with means of adjusting the damping force over a sufficient range to adapt it to the meter with which it is to be used. The adjustment should be smooth, permanent, and easy to use.

Figure 9. Demagnetization due to a d-c field as a function of coercive force



4. Economic Considerations

The size, weight, and cost of the magnet should be such as to make its use economically feasible.

5. Ease of Fabrication

The ease of fabrication of the material is important from the standpoint of uniformity, performance, and in keeping down variations between the magnets in large quantities.

6. Control of Magnet Quality

Complete control of the materials and processes is essential in order to produce high quality magnets in the numbers required.

Discussion of Available Materials

These specifications furnish an excellent basis for evaluating the materials in table I.

As has been previously shown, the requirement that the braking magnet have high inherent resistance to demagnetizing fields, particularly those resulting from lightning surges, can best be met by using a permanent magnet material of high coercive force (H_c).

The second basic magnetic property affecting the choice of material is the residual induction (B_r). It should be remembered that the cross section of a given magnet to produce a definite braking force will vary approximately inversely as the square of value of residual induction (B_r). The required length will vary approximately directly with the value of coercive force (H_c).

Based on these considerations, the outstanding materials in table I are the Alnicos, material No. 12, and sintered oxide, material No. 13.

Of these materials Alnico II represents the best balance, as it has high coercive force coupled with a good value of residual induction (B_r). Material No. 12 is of interest but is, as far as is known, not commercially available, the data having been taken from a United States patent as noted.

Material No. 13, composed of sintered oxides of cobalt and iron has a high coercive force but a low value of residual induction (B_r). The material is also very weak mechanically. These two limitations make it unattractive in comparison with Alnico II.

Actual Design

In considering materials and design of magnets, figure 15 is of interest as it shows in chronological order the watt-hour meter magnets made by one manufacturer from 1889 to 1940. The progress in design and utilization of materials can

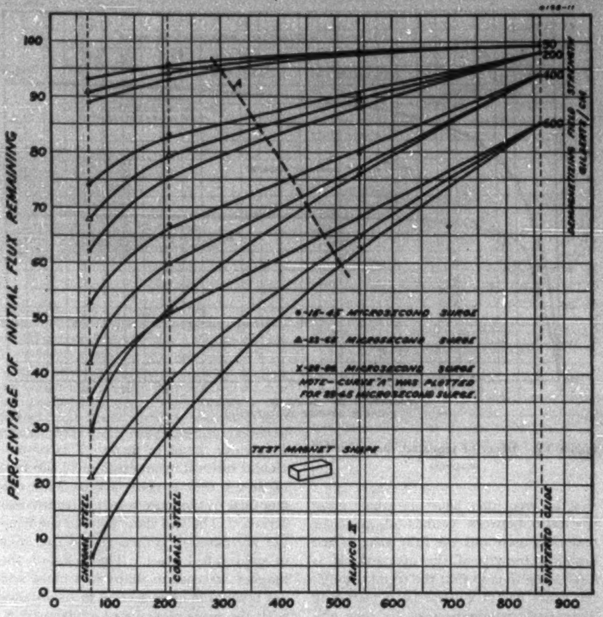


Figure 11. Surge demagnetization as a function of coercive force

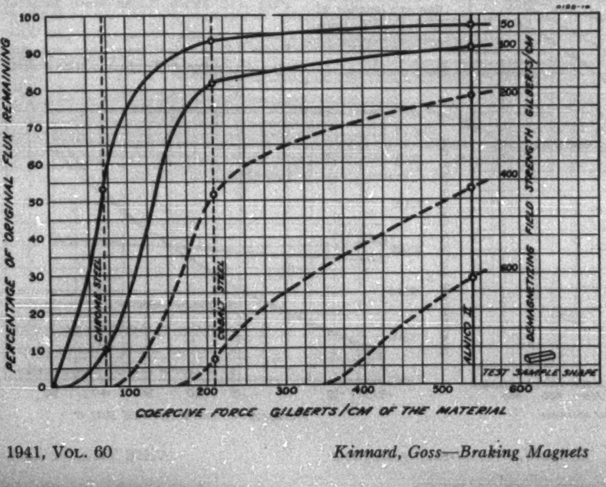
Note—Curve *A* was obtained by subjecting the chromium-steel bar magnet with a 0.002-inch thick copper coat to the same surges as were given the magnet without the coat. Compare curve *A* with the vertical line labeled "chrome steel"

Figure 10. Demagnetization due to a 60-cycle field as a function of coercive force



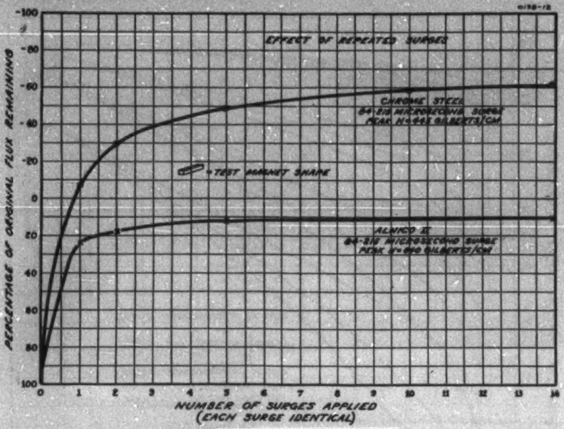


Figure 12. Effect of repeated surges on bar magnets

best be seen from figure 16 which gives the ratio between pounds of magnetic materials used and the fully magnetized braking strength of the magnet. It is interesting to note that the trend through the years has in general been markedly downward, culminating in the very efficient Alnico design shown in No. 10. The braking strength in figure 16 is measured in arbitrary units. For example, a single phase watt-hour meter requires a braking magnet of 515 points.

This magnet No. 10, which is shown in greater detail in figure 17, is of particular interest as an example of the type of design that is necessary to make efficient use of the more recent magnetic materials. The two short poles of the magnet are made of Alnico II and the yoke of cold rolled steel. The poles of the magnet are cast to shape in a mold and are tapered in cross section in accordance with the principles of design given by S. Evershed.[6] The steel yoke provides the return paths for the working flux and gives a rigid assembly with permanent air-gap dimensions. It also provides an excellent shield against demagnetizing fields of the lower frequencies.

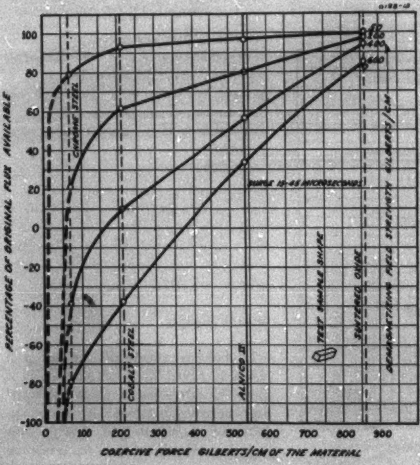

Figure 13. Ultimate surge demagnetization as a function of coercive force

A magnet of the type represented by No. 10 satisfactorily meets all requirements for a braking magnet. A high degree of stability against aging can be accomplished by proper heat treatments as shown by the lower curve in figure 6. High resistance to demagnetizing fields is inherent in this magnet because of the use of Alnico II, and temperature compensation can be satisfactorily provided as is seen from figure 14.

Due to the small size of such a braking magnet, it readily lends itself to great flexibility as far as interchangeability is concerned. It can easily fit into the space occupied by prior types of magnets and with the high magnetic energy available from the new materials, can readily be designed to have equivalent or greater braking force than the older magnets.

Summary and Conclusions

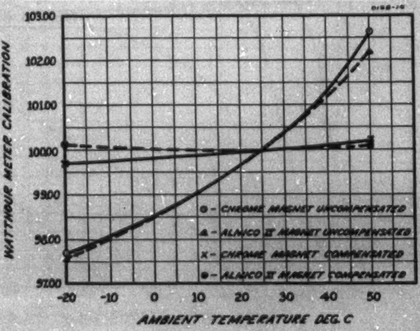
1. It has been shown that accurate methods of measuring changes in the effective flux and braking strength of watt-hour meter magnets are necessary in order to evaluate their characteristics properly. Methods of measurements have been described that are much more accurate than ordinary magnetic measurements and which can be depended upon to detect those changes to within 0.02 to 0.03 per cent.

2. In general, there seem to be two types of aging in connection with permanent magnets which may be classified as:

(*a*). Metallurgical aging
(*b*). Magnetic aging

For chromium steel magnets, metallurgical aging is of more importance whereas for Alnico magnets, the type of aging described as "magnetic" is the principal factor that must be guarded against by suitable stabilizing treatment. It has been shown that unstabilized magnets of chromium steel, cobalt steel, and Alnico exhibit some form of

Figure 14. Ambient temperature characteristics of a modern single-phase watt-hour meter



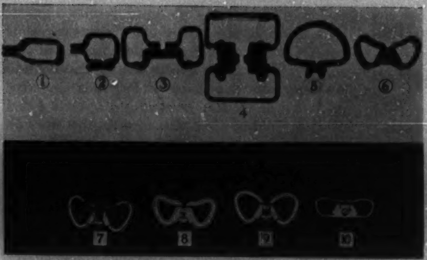


Figure 15. Historical review of watt-hour meter magnets of one manufacturer

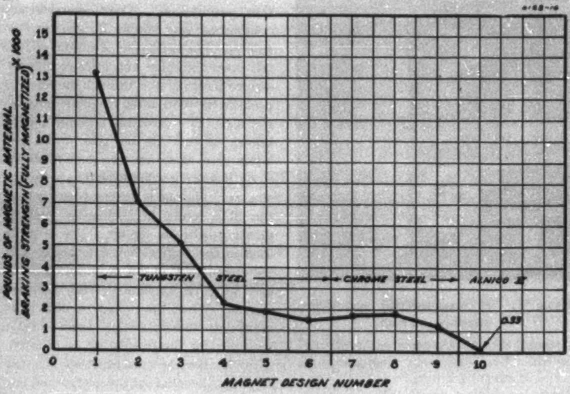
aging. Chromium steel and Alnico can, however, be suitably stabilized, and it is probable that cobalt steel and other materials can also be stabilized by proper treatments.

3. The ability of a magnet to resist demagnetization by fields varying from those caused by direct currents to lightning surges is shown to be a function of the coercive force of the magnetic materials. This relationship is shown quantitatively on standard bar magnets, and the great improvement that can be expected for watt-hour meter magnet application by the selection of high coercive material such as Alnico II is clearly shown by experimental data.

Figure 16. Weight of permanent-magnet material used to produce unit damping strength of the magnet designs shown in figure 15



High conductivity coatings such as copper are somewhat effective in protecting a magnet against high speed surges. When applied to the lower coercive materials such as chromium steel, the protection obtained is not so effective as is the use of a higher coercive force material such as Alnico.

4. Temperature compensation preferably by means of the conventional magnetic shunt must be applied to magnets made from Alnico the same as has been the practice with those made from chromium steel. It is shown that about the same degree of compensation is necessary and that this can be accomplished satisfactorily.

5. After the analysis of important characteristics, definite specifications are drawn up to assist in designing the best possible meter braking magnet and in choosing the best available material.

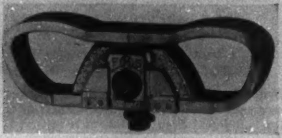


Figure 17. A modern watt-hour meter braking magnet using Alnico II

6. A design of a modern watt-hour meter braking magnet using Alnico II material has been shown to closely meet the specifications of an ideal magnet. The magnet is especially outstanding in regard to resistance to demagnetizing fields and possesses a high degree of permanency.

The Vertical-Flow Interrupter and Its Application to "Oil-Poor" Circuit Breakers

B. P. BAKER
ASSOCIATE AIEE

Synopsis: The historical background of the development of the vertical-flow interrupter for "oil-poor" circuit breakers is reviewed. A description of the interrupter and its theory of operation is given. The application of two of these interrupters to a 138-kv $1^{1}/_{2}$-million-kva "oil-poor" porcelain-clad circuit breaker is shown, together with laboratory test results.

A review is given of important field tests on a 138-kv single-pole unit, tested line to ground on a large 220-kv operating system up to approximately $2^{1}/_{4}$ million three-phase kva. Magnetic and cathode-ray oscillograms of these tests are shown.

OUTDOOR oil breakers with metal tanks have long been the accepted standard in this country, and they have met operating requirements satisfactorily except for a possible demand for lower oil content which would simplify maintenance and reduce fire hazard. The experimental development of an "oil-poor" breaker has been undertaken to determine the merits of this type of device. "Oil-poor" design naturally dictates porcelain-clad construction similar in type to that used in Europe. Conventional interrupters used in dead-tank breakers are not ideally adapted either electrically or mechanically to porcelain structures. It has therefore, been necessary to develop a new type of interrupter.

The conception of a controlled arc confined between corrugated walls of insulating material and subjected to the relative motion of an insulating fluid has proved effective, and the desire to retain the general principle has led to the construction of the vertical flow interrupter which will be described. Its physical characteristics and the small amount of arc energy which it liberates make it especially well adapted to porcelain enclosures.

Theory of Arc Extinction and Operation of the Vertical Flow Interrupters

In any interrupting device, the extinction of an a-c arc following a current zero depends upon the ability of the interrupter to transform the arcing space from a conductor to a good insulator before the circuit is capable of restoring voltage to the breaker terminals.[1] The time available for this voltage rise is a very small fraction of a cycle, usually so small that the insertion of finite objects, such as solid insulation or even liquids across the arc path is most difficult.[2] The conductivity of the arc is determined by the density of ionization in it during the time the current is flowing. Compton, Slepian, Saha and others have pointed out that the chief source of ionization is thermal and thus depends on high temperatures. Cooling the arc stream permits a greater rate of deionization. The rate of cooling depends upon the configuration and construction of the arc stream, that is its diameter and the distance from any point of greatest ionization to a relative cool object. It is thus apparent that when an arc stream is interspersed with cool volumes of gas, liquid, vapor, or un-ionized groups of molecules, these not only act as cooling centers but nuclei to which ions may migrate and become eliminated by diffusion and recombination.

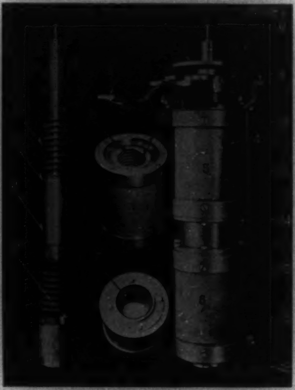

Figure 1. A two-interrupter vertical-flow assembly and parts

Assembly at right. Moving element (plunger) at left. Two views into interrupter well

From this very general review of arc-extinction theory it is apparent that an uncontrolled arc in an open body of oil or in an interrupter which allows the arc to surround itself with the relatively quiet atmosphere of a gas bubble, is going to be very slow in changing from a conducting state to that of a good insulator.

This theory suggests the necessity of limiting the random motion of an arc by surrounding it with corrugated insulating walls, and subjecting it to relative motion between it and a suitable fluid. There are two general means of obtaining relative motion between the arc and the fluid, first to hold the liquid in position and move the arc through it and second to hold the arc stationary and force the fluid past the arc. The former was accomplished very simply by stacking insulating plates with slots of various widths one upon the other and interspersing V-shaped pieces of iron through the stack to produce the motivating magnetic force on the arc. This structure is commercially known as the De-ion grid.[3,4] In the latter case there are two general directions of moving a fluid relative to an arc stream. The one is the cross-blast where the oil is forced in a direction perpendicular to the arc stream. The other is used in the vertical-flow interrupter and requires a flow of oil longitudinally to and in close proximity with the arc stream. When the motion of the oil is parallel to the arc stream, there is little tendency for the moving oil to interfere with the flow of current other than at zero, thus keeping the arc energy and gas generation low. At the same time the oil rapidly removes the excess gas from around the arc as fast as it is generated, so that as the current approaches its zero value the last little filament of arc may be regarded as passing through a small hole or chimney in the oil. Since the oil is under considerable pressure and adequate means is provided for the small amount of generated gas to escape freely, it may be assumed that the wall of oil surrounding the gas moves toward the arc as the arc space contracts with the

Paper 40-114, recommended by the AIEE committee on protective devices, and presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940. Manuscript submitted November 9, 1939; made available for preprinting July 8, 1940.

B. P. BAKER is circuit breaker development engineer, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

[1] For all numbered references, see list at end of paper.

decrease of current in the cyclic variation. Thus, when the diameter of the hole through the oil becomes small, especially near the current zero, the process of deionization by diffusion to the surrounding cool oil is greatly speeded up. Soon after the current reaches its zero value, and before the generated voltage can shift from the circuit inductance to the arc terminals, the ionization in the remaining gas is reduced to a very small value. Since the re-ignition or breakdown voltage through this last thread of gas varies inversely with the degree of ionization in the gas and directly with the absolute pressure on the gas, it is possible to interrupt a large number of volts per inch of arc length without danger of breaking the continuity of the arc path just preceding the normal current zero. This avoids any rapid increase in arc voltage and the subsequent voltage surges.

Description of the Vertical-Flow Interrupter

Figures 1 and 2 show a 138-kv interrupting element consisting of two vertical-flow units in series. Each interrupter consists of an insulating tube or cylinder with metal fittings at either end. The upper end of the cylinder forms a chamber into which the stationary contacts are built and is vented to the outside. The lower end is lined with fiber washers of different inside diameters, so as to form a corrugated well into which the moving contact and its corrugated follower is plunged upon opening. The follower completely fills the well except for a small opening on one side in which the arc is drawn. Upon opening, the metal cylinder just below the moving contact moves out of the well as the contact and follower move in. The area of this cylinder is less than that of the follower, therefore, as the arc is drawn down into the well, the oil in the annular space below the contact is forced vertically up past the contact through the small corrugated passage and made to flow parallel to and surrounding the arc, as previously discussed in the theory. The two interrupters are similar and when mounted in series form a single stationary assembly and a single moving assembly. When the breaker is closed the conducting sections of the moving and stationary assemblies are staggered to form a circuit from one end to the other. When the breaker is open they move into a position opposite each other. As many of these interrupters may be stacked one upon the other as required by the voltage rating of the breaker.

Breaker Structure

Figures 3 and 4 show the general construction of the single-pole-unit 138-kv vertical-flow "oil-poor" circuit breaker. It consists of two separate porcelain-clad compartments. The lower one is the insulation to ground and houses the current transformer. The upper one is the insulation between terminals and contains the interrupting elements and the oil disconnect.

The current transformer is supported on the floor of the lower compartment, the low-voltage terminals coming out through small bushings in the base and the high-voltage leads extending upward into the metal casing between the two porcelains. One of these leads comes out through the metal casing and forms one breaker terminal. The other is attached to the disconnecting member which on closing engages the interrupting element.

The interrupting element consisting of two vertical-flow interrupters in series is suspended from the top metal casing which forms the other breaker terminal.

The moving contacts are mounted on an axially located shaft which runs through the center of the interrupters and is biased toward the open position by springs located in the top metal casing.

In closing, the disconnecting member rises from the metal casing between the porcelains, moves about nine inches through oil where it engages the moving element of the interrupters, and carries it to the closed circuit position.

In opening, this sequence is reversed by first obtaining full separation of the interrupting contacts and then removing potential from them by inserting the disconnect gap.

The disconnecting gap is capable of withstanding full potential and is so arranged that a breakdown between ter-

10—Power terminal
11—Insulating tube surrounding operating rod
12—Insulating supporting tube
13—Oil-insulated current transformer
14—Oiltight stuffing gland around torsion shaft

With this construction no external disconnecting switch is required to remove voltage from the breaker.

The disconnecting member is operated by a set of straight-line levers located in the center metal casing, which in turn are operated by an insulating pull rod extending down through the current transformer compartment to a torsion shaft. This torsion shaft extends through a stuffing box and is operated through cranks and pull rods by an electric mechanism. The pull rod which passes through the transformer compartment is surrounded by a small insulating tube which connects the center metal casing with the metal base housing the torsion shaft. The oil in the upper porcelain which is used for interrupting can, therefore, be drained through the tube surrounding the pull rod and is entirely separated from the oil in the lower porcelain or current-transformer compartment.

The pole unit is separable in the center, allowing each compartment to be handled individually without disturbing the oil in the transformer case.

The interrupting element can be withdrawn from the top by removing the dome and removing four hanger bolts. The dome is held in position by springs which allow it to act as a pop valve in case of sustained arcing.

The entire structure is very rigid, consisting of metal base, central metal casing, and top metal housing. Between these parts are heavy Micarta tubes, one concentric with and inside of each porcelain. These tubes take all the mechanical shock, hold the porcelain in compression, and are capable of supporting the structure, retaining the oil and otherwise rendering the breaker operable even though the porcelains were broken or removed.

Interrupting Characteristics—Laboratory Tests

At the present it is impossible to obtain sufficient power in the most modern laboratories to make direct tests on high-power breakers up to their full ratings. Yet, there are several ways of approximating such tests and obtaining the interrupting characteristics of a circuit breaker.

The synthetic method of using a high value of current at a reduced voltage and then at the instant of arc extinction applying a higher transient voltage to give the equivalent of a high current and voltage, is sometimes used.[5,6]

Sometimes the interrupting characteristics of a device are obtained by testing over the entire range of available current at some given voltage and then choose some suitable current, and at this value of current determining the voltage limitation. The proper interpretation of these results may lead to correct conclusions, but much depends upon the characteristics of the device itself.

Whenever it is possible to subdivide the interrupter into its elemental units and test each to its limit, greatest certainty of results is obtained.[7] This method is ideally applicable to the vertical-flow breaker for 138 kv.

Tests on the 138-kv vertical-flow "oil-poor" breaker were made with first one and then the other of the two interrupters short-circuited by a heavy shunt. The results of these tests are given in figure 5, which show that a single interrupter (one-

Figure 5. Interrupting results using half of a pole unit

Figure 6. Representative oscillograms from data of figure 5

half of a two-interrupter assembly) can handle all values of current up to over 10,000 amperes at 44 kv; slightly less than 6,000 amperes at 66 kv; and over 4,000 amperes at 88 kv. Successful operations were also obtained at 1,000 amperes and 132 kv. The interrupting time is very constant over the entire current range and increases only slightly with increase in voltage. Since the arc is confined to the corrugated channel in which it is drawn and subjected only to the longitudinal flow of oil, which does not interfere greatly with the flow of current except near the zero value, the arc energy and external demonstration were very small. The oscillograms shown in figure 6 are representative of those from which the results of figure 5 were obtained, and show the almost negligible arc voltage so essential in "oil-poor" breaker construction.

If the arc voltage, arc energy, and therefore the mechanical shock are very small for one interrupter, it is reasonable to expect two interrupters in series to function satisfactorily and be capable of handling twice the kilovolt-amperes of one, providing the voltage is reasonably well divided between the two. In this breaker the greatest unbalance occurs with the top terminal grounded and the lower one made high, in which 40 per cent of the voltage appears on the top interrupter and 60 per cent on the lower one. With this impractical connection, a complete series of tests at both 132 and 88 kv was made. With the terminals reversed, where the division of voltage was perfect, no difference in the performance of the breaker could be detected.

Figure 7 shows the results of a number of interrupting tests on the single-pole 138-kv unit covering the current range up to 5,500 amperes at 88 kv and 3,000 amperes at 132 kv.

Figure 8 shows a similar curve for closing-opening tests at 88 and 132 kv on the 138-kv single-pole unit. It should be noted that the opening speed for the closing-opening tests was 11.7 feet per second, while the opening speed for the opening test was 9.3 feet per second.

Figure 9 shows two typical oscillograms on closing-opening tests, one at 88 kv and one at 132 kv.

All of the laboratory tests reported above were made on the 60-cycle basis.

Field Tests

Although the laboratory tests on this circuit breaker were rigorous and uniformly successful, it remains for field tests to verify conclusions and establish confidence in any entirely new design. This opportunity was offered through the courtesy of the Southern California Edison Company, who operate one of the largest 220-kv systems in the world. They permitted short-circuiting the heart of this system under load conditions up to 2,200,000 kva three phase equivalent at their Laguna Bell substation. During October of 1938, the single-pole 138-kv $1^{1}/_{2}$-million-kva vertical-flow "oil-poor" breaker was mounted near the center of of the 220-kv switchyard as shown in figure 3. The upper end or terminal was connected to one line of the 220-kv system and the other terminal was grounded as shown. The voltage across the pole unit was, therefore, approximately 124 kv.

Table I shows the results of the ten short-circuit tests made at powers varying from 200,000 to 2,200,000 kva calculated as a three-phase equivalent. At each power setting one opening and one closing-opening test were made. The current range extended from 540 amperes to 5,900 amperes rms measured at the point of contact separation and takes into consideration the d-c component of the asymmetrical waves.

logram records of these tests. Figure 11 shows the accompanying cathode-ray oscillograms. They indicate that for the lower-power tests the maximum instantaneous restored voltage reached 200 per cent of crest of the 50-cycle wave appearing across the breaker. The natural frequency of this oscillation was about 1,800 and 1,900 cycles per second. Its natural decrement reduced its crest value to that of the 50-cycle wave in approximately ¹/₄₀₀ of a second. This did not produce any evidence of voltage stress on the system.

For the highest concentration of power in which feeders from several stations were used, each seemed to have its own oscillatory frequency, resulting in a composite, with a maximum instantaneous value of 115 per cent above crest voltage and a natural frequency of the predominating harmonic of 700 to 800 cycles per second.

The total short-circuit duration varied from 3.4 to 3.6 cycles (50 per second) for the opening tests and from 3.8 to 4.4 cycles (50 per second) for the closing-opening tests. The relay time varied from 0.3 to 0.4 cycles (50 per second) and the time from rise of trip coil current to part of contacts varied from 1.8 to 1.9

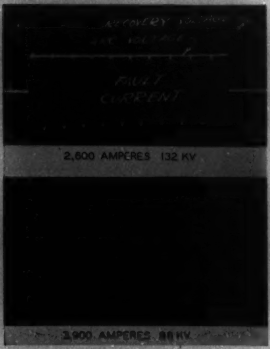

Figure 9. Representative oscillograms from data of figure 8

Figure 10. Representative magnetic oscillograms of the field tests tabulated in table I

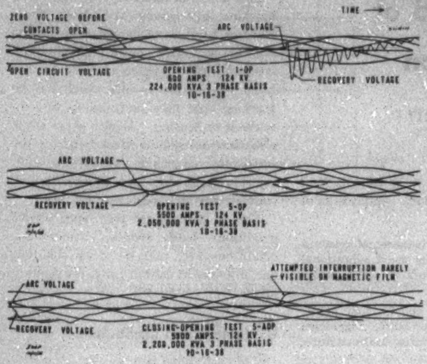

Figure 11. Cathode-ray oscillograms corresponding to the magnetic oscillograms of figure 10

cycles (50 per second), thus leaving an arcing time for the opening tests of from 1.3 to 1.5 cycles and a closing-opening arcing time from 1.6 to 2.2 cycles.

The increase in arcing time of the closing-opening tests over the opening tests does not appear consistent with results obtained in the laboratory where the breaker was allowed to close in and latch before opening. While the contacts closed far enough to touch and carry the current before reversing, they did not go entirely closed and thus the contact speed over the arcing period may have been slightly low. Even though they did not slide into full engagement which consists of over an inch of lap, enough contact was made to demonstrate their ability to close in on a short circuit and carry current if time delay relays were used.

The arcing time as a function of current for this set of tests is plotted in figures 7 and 8. The points are superimposed on the laboratory results, to show the consistency of operation over the entire range of current. The contact speed for the field tests was 12.5 feet per second while for the laboratory tests it varied from 9.3 to 11.7 feet per second. Also, the time from rise of trip coil current to part of contacts was 2.3 cycles for the field tests, whereas it was slightly less than 2 cycles for the laboratory tests.

The contact separation at the point of arc extinction varied from $3^1/_4$ inches to $5^3/_4$ inches. Therefore, for the two breaks in series the maximum volts interrupted per inch of contact separation or inch of arc length (since there is no looping of the arc) is almost 20,000 volts.

Recording meters placed on the customer's system indicated a very low dip in the system voltage, with no loss of synchronous load.

Preceding the first series of six tests and the second series of four tests, the interrupting compartment of the breaker was filled with clean oil (approximately 60 gallons). After the tests very little carbon was visible either in the oil or on the interrupters. The oil tested 27 kv with a standard test cup.

The contact resistance was measured before and after each series of two tests, consisting of an opening and a closing-opening test, and found to remain constant at 0.00086 ohm. Inspection of the breaker after the tests also indicated that the contacts as well as all other parts were in excellent condition.

Throughout the entire series of tests the external demonstration was negligible, no jump, vibration nor evidence of high internal pressures. On the heaviest power interruptions there was only a slight whiff of smoke to be seen with not a trace of soot or oil around the opening of the muffler.

Again, it is a privilege to thank the engineers of the Southern California Edison Company for their co-operation in making possible such extensive tests on a circuit breaker in which they may have only an academic interest.

No description of this development would be complete without a word of appreciation for the assistance and co-operation given in this development by the engineering department and by Doctor J. Slepian and his research group.

Conclusions

The vertical-flow interrupter possesses many desirable characteristics. Intensive testing under laboratory conditions, supplemented by field tests on a heavy concentration of power, indicates that within the range of currents encountered in American practice from 132 kv and upward its performance may prove to be very acceptable.

The "Black Band" Method of Commutation Observation

T. W. SCHROEDER
ASSOCIATE AIEE

JOHN C. AYDELOTT
MEMBER AIEE

Synopsis: Good commutation is essential for the reliable performance of d-c machines with low maintenance costs. As an aid to the commutation adjustment of machines in the factory, or in the field, a systematic test procedure has been found useful on large machines to indicate certain features of the machine's adjustment, notably the commutating field strength and brush position. This information is obtained directly from curves known as "black bands" or "buck and boost curves" plotted from test observations. The significance and interpretation of these curves in terms of machine adjustments, differential between commutation-reactance voltage and voltage induced by interpole flux are presented and results of observations on machines for special service (variable-speed motors and variable-voltage generators) are also given in this paper. Included are typically shaped "black bands," obtained in practice. The black-band method has proved to be an extremely powerful and useful tool in commutation adjustment and it is hoped that this discussion of it will lead to an increasing use of the method with a corresponding furtherance of knowledge about it, thus enlarging its scope of usefulness.

The Commutation Problem

ONE of the most important problems in the satisfactory operation of d-c machines is that of obtaining successful commutation. This problem has always been one requiring considerable attention because of the numerous factors influencing commutation, many of which are difficult to evaluate. A detailed discussion of these many factors is beyond the scope of this paper, but a brief tabulation of them here will be an aid to an appreciation of the part black-band tests play in the solution of the commutation problem. The factors may be divided into four main groups:

(1). Mechanical condition of rotor
(2). Brush conditions
(3). Atmospheric conditions
(4). Electrical and magnetic conditions

Breaking each of these groups up and naming a few of the many components of each, we have:

Under (1) mechanical trueness of commutator surface at operating speed, vibrational tendencies of rotor, condition of mica between commutator bars.

Under (2) brush top and bottom angle, brush-grade material, pressure, alignment, spacing around commutator, and condition and type of springs.

Under (3) humidity and temperature, presence of oil, oil vapors, paint, acid fumes, abrasive or chemically active dust, or steam in atmosphere.

Under (4) brush position, commutating field strength, commutating pole tip and gap.

The black-band method of commutation observation is important because it gives a measure of the commutating ability of a d-c machine. In other words, the black-band method is a sort of "commutation meter" which gives a more accurate picture of the commutation performance of a machine than is obtainable by other methods. Analysis of black-band observations give a measure of both the overload and transient load-commutating ability of a d-c machine, as well as indicating certain features of the machine's adjustment and design such as brush position, commutating field strength, and commutating zone width.

Significance of the Black-Band Method of Commutation Observation

This method of judging commutation performance derives its name from the zone of variable commutating field strength at any load, in which commutation will be sparkless or black. This zone is obtained by first opposing (bucking) then aiding (boosting) the load current flowing through the commutating field coils at any value of load on the machine, and plotting curves against load of amperes boost and buck at which light general sparking just begins. The resulting curves represent a band between the limits of which commutation is black, hence the name "black band." A black band on an ideal machine from a commutation performance standpoint is shown in figure 1.

It is not to be inferred, however, that a machine must operate at all loads within its black band, as successful commutation does not necessarily mean perfectly black commutation. A machine which commutates successfully is one which has no sparking that may be injurious to commutator or brushes. Hence, operation of a machine outside its black band may be satisfactory as long as the sparking is not injurious and does not cause excessive commutator and brush maintenance.

This is particularly true since service conditions—load swings, atmospheric conditions, etc., may be so variable that one adjustment cannot fulfill the requirements of all conditions.

Usefulness and Limitations

Black bands are useful both in adjusting new machines for proper commutation, and in determining what the difficulty may be with machines in service which are giving commutation trouble. They are far from infallible, and because of the many variable factors involved, occasionally a band is obtained which seems difficult to interpret in the light of present theory on this subject. Certain generalizations can be made, however, and more knowledge about them should be obtained as time goes on.

One of the limitations of black bands is that integrity of observation and recording is required to judge equally both upper and lower limits of the band, to assure determination of the true band center and proper band width. Since the band limits are taken by eye, they may tend to vary with observers. Another limitation is that it is sometimes difficult to determine the band limit if sparking is not uniform on all the brushes. This cannot be considered strictly a limitation since it is possible, if circumstances warrant, to set up a commutation grading system whereby the sparking condition of each brush is weighted. On machines with large numbers of brushes, however, this procedure is usually not practicable. If a single stud on a machine or a few brushes on a stud are limiting the band width, investigation should be made to correct the condition which is faulty about this stud, and eliminate its early sparking.

For a band to present a true picture, so that a very similar band could be obtained if observations were made a second time with conditions unchanged, the commutator film should be well established and stable; and the brushes must be well fitted to the commutator, have a good polish, and be free from any tend-

Y., and is now in the central station engineering department of the same company; J. C. Aydelott is engaged in railway motor design for the General Electric Company, Erie, Pa.

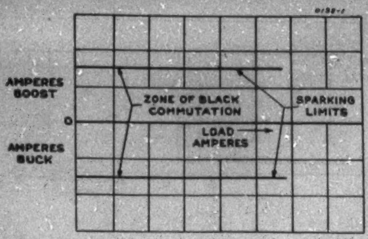

Figure 1 (left). Ideal black band

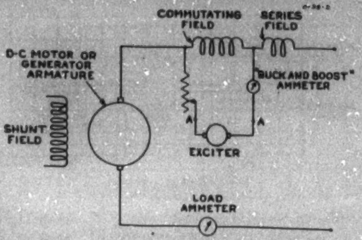

Figure 2 (right). Connections for taking black band

ency to vibrate or to change position in their holders ("take a multiple seat"). For design comparison of machines it is possible to partially control this commutator surface and brush condition by the use of a light application of brush seater on the commutator just before taking the black-band readings. This is not desirable for final adjustment, of course, where the band should be taken with the commutator and brush conditions as nearly as possible the same as those the machine will have in actual service.

Instructions for Taking Black Bands

In order to take a black band on a machine, it is necessary to vary both the load and the commutating field strength. For variation in load, the machine may be loaded on a water box or connected "pump back" if duplicate or similar units are available. For varying the commutating field strength a variable-voltage power supply of sufficient capacity is connected across the commutating field winding (and compensating or pole-face winding if one is present and it is interconnected with the commutating field winding) of the machine under observation. The most convenient type of variable-voltage supply is an exciter, the armature of which is connected through a water box or other suitable variable resistance to the commutating field terminals as shown in figure 2. The buck-and-boost current can then be varied both by the resistance in the armature circuit of the exciter and by field control of the exciter.

A convenient method of determining whether the ammeter is connected to read "buck" or "boost" is to disconnect the exciter lines at *A* in figure 2 and, with a low value of load on the machine, short the lines from the commutating field together, thus shunting some current around the commutating field. If the ammeter reads up scale, it is connected to read "buck" current.

Load should never be quickly removed from a machine which has buck or boost on it, as this may result in severe sparking and damage to the brushes and commutator.

The determination of the band limit at any load is a matter requiring some judgment on the part of the observer. If one or two brushes begin to spark slightly, and the buck-or-boost current can be increased considerably before otherwise general sparking begins without excessive sparking on the part of these few brushes, it would probably be best not to give much weight to these brushes in determining the black-band limit. When taking bands on machines with compara-

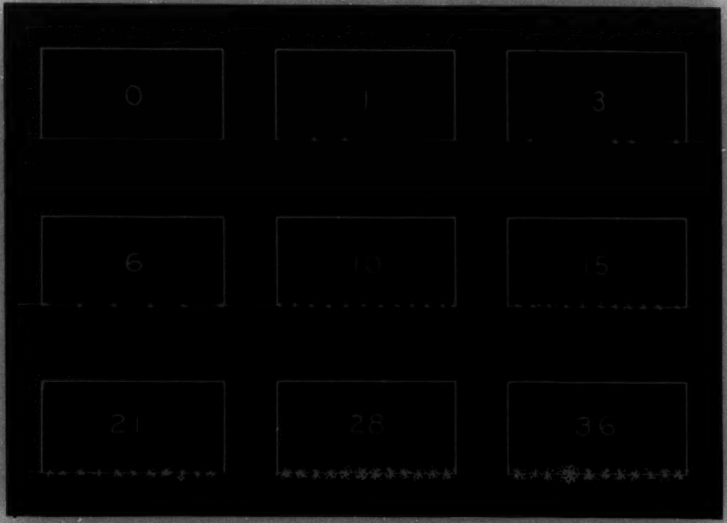

Figure 3. Sparking chart

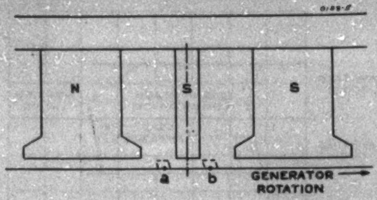

Figure 5 (right)

tively few brushes, a note should be made on the curve sheet regarding the sparking condition of each brush at the band limit decided upon.

The above-described method of obtaining band limits will probably be satisfactory for most cases, but it may not suffice for some conditions of machine load, speed, or voltage where the black band may be either very narrow or even nonexistent. For these conditions a refined method of accurately determining black-band limits, or of finding a band of minimum sparking (useful for adjustment of a commutating field strength and brush position where there is no black band) is necessary. If need for such a method arises, the following commutation grading system may be used:

Figure 3 illustrates various degrees of sparking to which arbitrary numerical values have been assigned representing as nearly as possible the amount of energy in the sparks or the amount of burning which the sparks will produce on the commutator. This grading system has been used very successfully for several years in building motors for transportation service in the General Electric Company. Each individual brush should be graded for a given set of conditions, i.e., for a particular load and particular amount of buck or boost. The average of these numerical values will fairly represent the over-all sparking of the machine. When there is no black band, it is desirable to traverse the whole range of buck and boost from fairly bad sparking at one extreme to similarly bad sparking at the other extreme. Such traverses should be made consistently with either falling commutating field strength or rising commutating field strength in order to avoid discrepancies in results due to hysteresis in the magnetic circuits. In making a traverse the range of buck and boost is divided into a suitable number of steps and each step is held until all the brushes have been graded. The process is repeated for each step and the results averaged and plotted. From these data the condition of best commutation can be determined accurately even if there is no black band. Such points of best commutation for various loads on the machine will line up as a continuation of the center line of a black band and a line connecting them can be used in a similar way to that in which a black band is used.

A good black band may be obtained by "bucking and boosting" the commutating field at but four or five load points including no load on a generator (running light load on a motor) and the maximum load at which the machine may be run long enough to get black-band points.

Theoretical Effects of Various Factors on Black Bands

The adjustment of a machine, principally its brush position and commutating field strength, as well as some design features, such as the width of neutral zone, commutating pole gap, and tip width, have certain theoretical effects on the black band. A knowledge of these effects is essential to the interpretation of the band.

1. Brush Position

Consider a brush ahead of neutral on a generator as at *b* in figure 5. Commutation is aided by flux from the main south pole, hence the amount of *buck* which may be applied to the commutating field before sparking begins at no load is greater than the amount of *boost* which may be applied, see figure 4*B*. If the brush is behind neutral, as at *a* figure 5 the main north pole flux *hinders* the commutating pole flux hence more *boost* than *buck* may be applied as in figure 4*A*. Similar reasoning is gone through for motor action with opposite results since the commutating pole shown in figure 5 becomes a north pole for a motor. With brushes on electrical neutral the black band is symmetrical about the zero point at no load. This is borne out by black bands taken on many reversing-type motors, whose brushes must be on electrical neutral (brush position giving same full-load speed with fixed shunt-field excitation, both rotations). They have shown the no-load points symmetrical about the zero axis.

2. Commutating Field Strength

A tilted black band with no-load points centered, as shown by the solid lines in figure 6 indicates brushes on electrical neutral but too weak a commutating field since the amount of boost which can be applied increases uniformly with load. Conversely, a downward tilted black band as shown by the dotted curve indicates too strong a field. This can be swung into the desired horizontal position, as shown by the dashed curve, by shunting a proper amount of current from

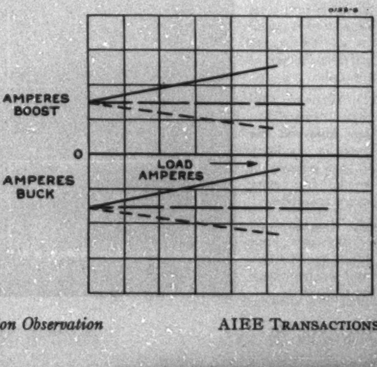

Figure 6. Effect of commutating field strength on black bands

Solid-line band—commutating field weak

Dotted-line band—commutating field strong

Dashed-line band—commutating field correct the commutating field, or reducing the commutating field strength by substitution of nonmagnetic for magnetic shims under the head of the commutating pole.

If the black band is horizontal but displaced upward for a motor, as shown in figure 7, it indicates a proper commutating field adjustment because it is horizontal but the brushes ahead of neutral as indicated by the displacement of the no-load points, see figure 4*A*. Such a band might continue out to a very high value of load, as discussed later. This may also be tilted by changing the commutating field strength and can be centered by shifting brushes.

3. Black-Band Width and Closure

The wider the black band, the greater may be the variation in commutating field strength from normal before visible sparking occurs. A wide band is desirable, obviously at all loads at which the machine will operate, so as to have black commutation during transient load periods, when the commutating field flux lags the armature current slightly due to hysteresis and eddy current effects in the magnetic circuit. A wide band also gives greater margin for changes in commutator film, brush riding conditions, etc., without getting into commutation difficulty.

Under normal commutator film and brush riding conditions, it is felt that the distribution of the neutral zone flux used for commutation (this may consist of commutating pole and main pole fringing flux) is one of the most important factors determining the width of the black band and its closure with load. How the commutating pole-tip width or gap length affects band width is not clearly known except that there are optimum conditions for both and any divergence therefrom makes the black band narrower than normal.

A black band of normal width based on experience with machines above 300 horsepower appears to have a total spread of boost plus buck in per cent of rated load amperes at rated full-load current about in accordance with the following table:

Commutator Peripheral Speed (Feet Per Minute)	Commutating Field Current, Boost Plus Buck at Full Load in Per Cent of Rated Full-Load Current
Machines 300 to about 1,000 horsepower	
1,000	10 to 20
5,000	1.5 to 5
Larger machines	
1,500	5 to 10
5,000	1 to 4

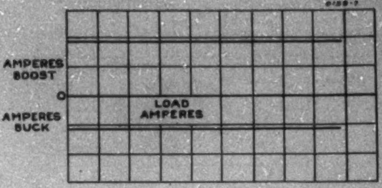

Figure 7. Black band for a motor with correct commutating field strength but brushes ahead of neutral

Data for this table were obtained from black bands taken on 30 variable-speed motors at both base and top speeds. A scatter curve of band width against commutator peripheral speed was plotted, and the limits indicated were obtained.

4. Differential Reactance Voltage

The black-band curve is of assistance in studying a quantity called differential reactance voltage. This voltage is defined as the difference between the commutation reactance voltage (the voltage in the coils undergoing commutation by virtue of the current changing from a positive to negative value through the inductive armature coils) and the counter voltage induced in these coils by the commutating pole flux, to promote the change of current. In an ideal machine, the differential voltage is zero at all loads, since the magnitude and space or time distribution of commutating voltage is such as to completely cancel the reactance voltage at each point in the commutating zone. If the differential voltage is not zero, because these conditions are not met, it varies directly with load. To show this, assume that at full load on a machine the average voltage induced in the coils undergoing commutation is 90 per cent of the average reactance voltage. The average differential reactance voltage is, therefore, 10 per cent. Both of these voltages are proportional to load current (if the commutating pole circuit is not saturated), so at half load the commutating voltage would be 45 per cent and the reactance voltage 50 per cent with the differential reactance voltage 5 per cent or half of what it was at full load. The effect of main-pole fringing flux is to produce a differential reactance voltage proportional to it at any value of load.

The relationship between this differential reactance voltage and load may be obtained by drawing on the black-band curve a line dividing the band, as nearly as possible, into two symmetrical halves, as line *a–b*, figure 8*A*. In this case the brushes are on neutral, so point *a* of the line is at the origin. Since the brushes are on neutral, there is negligible pole-fringing flux in the commutating zone and the differential reactance voltage is proportional to load. If the brushes are

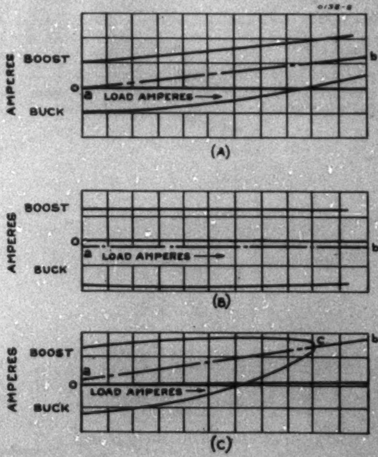

Figure 8. Reactance-voltage lines for various black bands

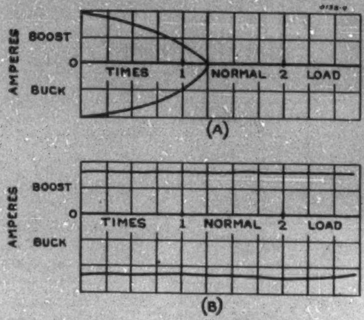

Figure 9 (left). Effect of slight brush shift (B) on some motor bands such as (A)

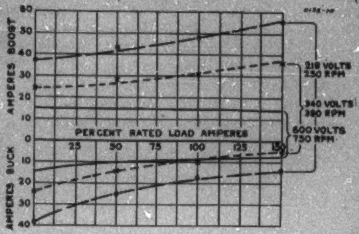

Figure 10 (right). Black-band curves on 1,000-horsepower 250/750-rpm 600-volt reversing motor showing effect of speed with constant main-pole flux

off neutral, point *a* of the line which strikes the no-load ordinate midway between the band limits is not on the origin but is displaced as in figure 8*B*. In this case the differential reactance voltage line is seen to be a constant distance away from the zero axis; this is because the differential reactance voltage is being caused by main-pole flux which does not vary with load.

It is interesting to note that the differential reactance voltage line coincides with the line of best commutation at loads beyond the point of closure of the black band, as line $c-b$ on figure 8*C*.

Observations in Practice

The use of black bands for observing and recording commutation performance for several years has led to certain useful practical conclusions regarding their interpretation and value in adjusting machines.

1. Band Width and Closure

The ideal black band is one that is symmetrical about the zero axis of buck and boost, and is wide open out to a large value of load, as shown in figure 1. It is not always desirable, however, to set the brushes on electrical neutral to get no-load band symmetry, as this sometimes causes a band to close up early as in figure 9*A*. Often on a motor a slight backward shift of the brushes causes 9*A* to become 9*B*, which is, of course, a better band from the standpoint of overload commutation and band width. If, on a reversing motor (where brushes must be set on electrical neutral) the overload commutation is required to be better than that shown by figure 9*A*, it is necessary to improve such a band by commutating field adjustment, commutating pole-gap change, etc.

The closing of a well-centered band under heavy load may be due to the mechanical problem of commutating or even conducting large currents. Greater heating at high load may affect brushes, commutator, and the resistance of armature coils undergoing commutation. Closing may also be due to differential reactance voltage increasing with load until at heavy loads the brush is no longer able to absorb it.

It has been observed that on some d-c motors a spark persists on the "leading" or "entering" edge of the brush regardless of the commutating field strength (value of buck or boost), and that this sparking could be obviated only by a narrower commutating pole tip or a decrease in commutating pole gap. "Trailing" or "leaving" edge sparking does not appear to be critical of commutating pole-tip width unless the rotation of the machine is such that the *last* conductor to commutate in a slot is a *top* conductor.

2. Commutating Pole-Circuit Saturation

A sudden tipping up and closing of the black band at a large value of load may indicate saturation in the commutating pole circuit, or brush characteristics associated with current density. To find which of these causes may be giving such a band, it is customary to remove half the brushes on the machine and take another band out to half the maximum load current to which the first band was taken. This permits the same brush-current density for the band, but the commutating pole-saturation effect should be absent if that is the trouble. This test is not conclusive, however, because of the possibility that the tipping up of the band is caused by changed flux-leakage conditions at the higher loads. As a further check, a commutating pole-saturation curve with the machine under actual load may be taken, using a fluxmeter to measure commutating pole flux.

Special Observations

To obtain further information concerning black-band characteristics on machines under varying operating conditions,

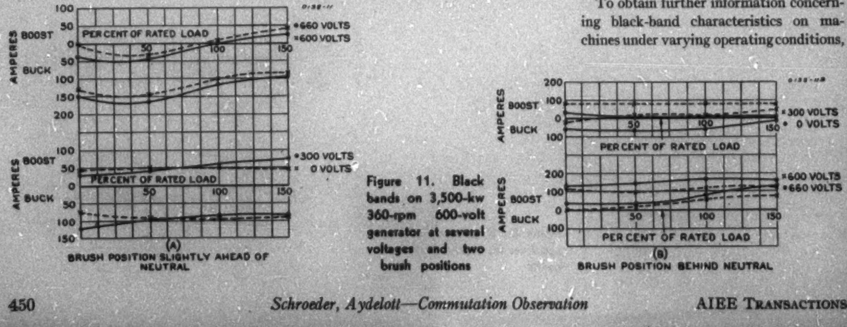

Figure 11. Black bands on 3,500-kw 360-rpm 600-volt generator at several voltages and two brush positions

a series of special tests were made. Two of these tests, one on a variable-speed motor and one on a variable-voltage generator, are here discussed.

1. Band Width and Tilt Versus Speed, Variable-Speed Motors

It has been found that the black band of a variable-speed motor is always narrower at top than at base speed. Further it is necessary on variable-speed motors to adjust the commutating field a little strong at top speed so that it will be only slightly weak at base speed; in other words, the effect of the commutating field, all other things being equal, increases with speed.

To determine whether or not a change in main-field fringing flux was partly responsible for these conditions, a test was recently made on a 1,000-horsepower 250/750-rpm 600-volt motor. As this was a reversing motor, brushes were on electrical neutral. Black bands were taken at 250, 390, and 750 rpm by varying the terminal voltage, thus keeping the same main-field flux condition for each speed. To hold constant flux at all speeds, it was necessary to hold normal top-speed field current, in order not to exceed rated voltage at top speed. The bands are shown in figure 10. The band at top speed was narrower than the one at base speed, and the band shown for 390 rpm and 340 volts was almost identical with an earlier band taken at 390 rpm and 600 volts. Hence, it appears that with brushes on electrical neutral, main-field fringing flux has little effect on black-band width. It will be seen that the commutating field strength, which was about right for 750 rpm, apparently decreased with speed (tipping up of black band increased).

2. Effect of Brush Shift on Generator Bands at Various Voltages

To show the effect of shifting the brushes on a generator off neutral on black bands taken at various generator terminal voltages, such bands were taken on a 3,500-kw 360-rpm 600-volt generator designed for Ward Leonard control. The bands are for generator action, two brush positions, 660, 600, 300, and 0-volts terminal. Figure 11*A* is for brushes ahead of neutral, and figure 11*B* for brushes behind neutral.

Figure 11*A* shows that with decreasing generator terminal voltage the no-load points of the band move more and more in the boost direction, until at zero voltage the band is nearly centered. The brushes are under the influence of fringing flux from a main pole of polarity like that of their commutating pole and as the main flux (generator terminal voltage) decreases this influence decreases also until at zero main-field flux the band is nearly centered in spite of the brushes being off neutral. Figure 11*B* shows the same effect in the opposite direction for the brushes behind neutral. Again at zero-terminal voltage the no-load band points are nearly centered.

As a result of these tests, it has been suggested that the proper way in which to adjust a machine too large to be loaded in test is to set the brushes for no-load band symmetry at rated voltage, then adjust the commutating field for a centered band at normal load current with the machine driven as a generator, terminals short-circuited.

Conclusion

When the black-band method is used in the systematic adjustment of a machine for best commutation, it removes much of the uncertainty and variability of commutation. While the black band indicates directly only brush position and commutating-zone magnetic conditions, it also indicates indirectly, some information regarding stability of commutator film and friction, a phase of the commutation problem which must still be solved largely by experience.

Increased Capacity and Interconnections of the Columbia Gas and Electric Corporation

C. W. DeFOREST
FELLOW AIEE

Introduction

THE electrical properties operated by the Columbia system are located in the southwestern quadrant of Ohio and in northern Kentucky. These properties are shown in figure 1. The actual operations are carried on by the Dayton group, and the Cincinnati group.

The principal loads served are in Cincinnati, in or near Dayton, Ohio, and in the industrial towns of the Great Miami Valley, lying between Cincinnati and Dayton. In the period from 1918 through 1939, the load has grown from 70,000 kw to 360,000 kw. To meet this increase in load, there was in progress almost continuously a program of increase in generating capacity and interconnections. The program is shown on the chart of figure 2. The growth of summer load in late years has increased the required reserve capacity and somewhat accelerated the whole expansion program.

Transmission and substations to serve the load were developed along with the additions to capacity. This development was influenced by operating experiences which included system instability, bus faults, and floods.

Generating Stations

In 1916 the principal generating stations of the area were Third Street and Fourth Street stations in Dayton, the Plum Street station in Cincinnati, and Newport station in Newport, Kentucky. The rapid growth of load during the war required increase of generating capacity in both localities. The Dayton and Cincinnati stations obtained their condensing water from the Miami-Erie Canal. This canal was ultimately to be abandoned so that it was necessary to provide not only for additional load, but to plan new stations on new sites to provide for the ultimate loss of these existing plants.

Millers Ford Station

Wolf Creek, the Stillwater River, and the Mad River, a spring fed stream, flow into the Miami River at Dayton and, therefore, the Miami River offered a good supply of cooling water. Railroad facilities were available at the point where the Big Four Railroad crossed the Miami

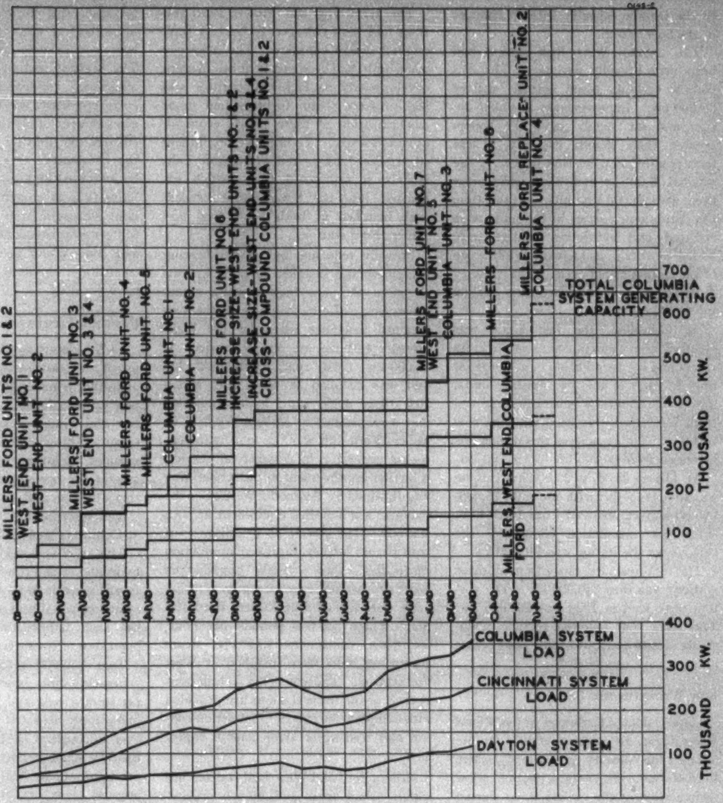
River at the south city limits of Dayton. The site was close to the load center and was within the Miami conservancy district which provided protection against flood of the river. It was decided to develop the new Millers Ford station at this point. The ultimate development was considered for 100,000 kw, with an initial installation of two 12,500-kw units. The steam conditions were 225 pounds per square inch and 550 degrees Fahrenheit. Construction was started in 1916 and the first two units were put in operation in 1918. From this time until 1924 three 20,000-kw units were installed to bring the total installed capacity of the station to 85,000 kw.

West End Station

In the Cincinnati area, the Ohio River provides an ample supply of good water for power-station condensers. Rail facilities are available on the Ohio side of the river from the east end of Cincinnati to the Indiana state line on the west. The river itself was available for transportation of coal from the West Virginia fields. The company owned property along the river upon which was located an artificial gas plant. This plant had been rendered obsolete by the introduction of natural gas to this region. The site, near the load center, approximately one mile southwest of the center of the business district, was chosen for the location of the new West End station. The station was designed for an ultimate capacity of 100,000 kw in four 25,000-kw units. Two units were installed in the initial installation. The steam conditions were 600 degrees Fahrenheit and 260 pounds per square inch. Construction was started in 1916. A principal problem in the design of this station was to allow for operation through the wide range of river elevations. Government records give flood stages as far back as 1832. The most severe flood on record had occurred in 1884 when the river reached a stage of 71.1 feet. The design level of West End station was set at one foot above this maximum flood stage. However, the design was such

Figure 2. Increase in load and generating capacity of the Columbia Gas and Electric Corporation



that by doing some emergency work, the plant could operate through floods rising several feet above this level. Condensing water must be handled through the entire range of levels. The most economical operation is obtained by locating the condensers at the low water level of the river. To accomplish this, condenser-well construction was used. This was one of the earliest stations to be so constructed. The first unit was completed in 1918, the second a few months later in 1919. The fourth unit was put in operation at West End in 1921. This brought the station to the 100,000-kw capacity for which it was originally designed.

Columbia Station

. The Cincinnati company then sought a new site for capacity to meet its continually growing load. Extensive studies were made of a mine-mouth steam plant, of southern mountain hydro sites, and of a new Ohio River steam plant. Transmission studies were made and the economics of each project thoroughly investigated. However the final analysis resulted in the selection of the site of the present Columbia station which is on the Ohio River, 20 miles downstream from Cincinnati. This location had practically unlimited space and facilities for future development. Coal could be received and handled conveniently by rail or barge. The river provided an excellent condensing water supply. Located as it is at the Indiana state line, it served to establish the territory of this system to that point. Transmission lines could be brought out of the station in any direction desired. ~~The station coal~~ storage, crib house, and discharge and intake tunnels were designed for an ultimate capacity of 320,000 kw. The initial installation consisted of two 45,000-kw units. The first unit was completed in the fall of 1925 and the second in the spring of 1926. These were tandem compound units operating on a reheat cycle with inlet steam at 725 degrees Fahrenheit and 600 pounds per square inch. The boiler plant of this station was the first to be initially designed for pulverized coal fuel.

Further Increases

The next increase in generating capacity came in 1928 and 1929. This program involved all three generating stations. All three stations had an excess of boiler capacity and it was possible to add to the turbine capacity without changes in the boiler room.

The original West End station had been very liberally designed. The 25,000-kw turbines could actually deliver 35,000 kw. Improvements in stoker design and air supply gave the boilers greater than design capacity. These facts resulted in a decision to remove the original 25,000-kw generators and replace them with 36,000-kw units. At this time the diaphragm nozzles in the units were changed and extraction heaters were added to obtain an increase in efficiency of the station-steam cycle. The capacity at this station was increased from 100,000 kw to 144,000 kw.

At Columbia, the installation was changed from tandem compound to cross compound by the addition of a 16,000-kw unit to each of the two existing units. Two of the 25,000-kw generators removed from West End were used with the new turbines. The capacity of this station was increased from 90,000 kw to 126,000 kw.

At Millers Ford, a 25,000-kw turbine was added together with one of the 25,000-kw generators removed from West End. With this installation completed, the capacity of the station was 110,000 kw.

The total installed capacity in all three stations was then 380,000 kw. The system peak load in 1929 was 261,000 kw. The years that followed brought a decrease of load and it was some years before new capacity was needed.

Low Water in the Miami

Unprecedented low water in the Miami River during the summer of 1934 greatly reduced the capacity available at Millers Ford station. To create a pool and allow recirculation of the cooling water during low flow, a dam was built in the river during the following year. It was thought that the pool temperatures would rise above that of the river. However, when operated, it was found that the cutoff piling of the dam which extended 13 feet below the river bed forced ground water up into the pool and dropped the temperature to five degrees Fahrenheit or more below that of the river flow. The full capacity of the station was restored by the dam.

Modernization of Old Plants

The growth of load in 1934 and 1935 indicated a need for an increase in capacity. Construction undertaken in the latter year had as its major objectives the improvement in efficiency of the production facilities and the elimination of the existing hazards in the switch rooms of the generating stations.

The West End and Millers Ford stations had been enlarged to beyond their original design capacity. The efficiency when built, had been excellent but modern developments in high-temperature and high-pressure steam turbines had made modernization of these plants economically attractive. To improve production efficiencies 1,200-pound 900-degree Fahrenheit superimposed units which exhausted into the low-pressure headers were installed at both West End and Millers Ford stations.

Pressure reducing and desuperheating equipment was installed at both stations to make the new high-pressure steam generating capacity available to the low-pressure machines whenever the high-pressure turbines are out of service. A 36,000-kw, 3,600 rpm, hydrogen-cooled unit was installed at West End, and a 30,000-kw, 3,600 rpm, hydrogen-cooled unit was installed at Millers Ford. The Millers Ford unit was the first hydrogen-cooled generator in commercial service. A further improvement in plant operation was obtained by the modernization of the coal and ash handling equipment at both stations. The new boiler installations at both plants further improved production efficiencies. Two 375,000 pounds per hour, dry-bottom type, steam generating units were installed at Millers Ford station. Three 350,000 pounds per hour, open-pass, continuous slag-type steam generating units were installed at West End station. The new boiler installations at each of the three stations are provided with complete automatic combustion control and feed-water level control equipment.

Millers Ford and West End stations are within urban areas and fly-ash precipitators were consequently installed at these stations. Cottrell-type precipitators operating on single-wave rectification were installed.

After the 1929 generator changes, in which the capacity of the units at West End station were increased from 25,000 to 36,000 kw, the original condenser design did not permit peak capacity at times of maximum river temperature. This was corrected in 1936 by a redesign of each of the condensers. These units are of the vertical tube, two-pass type, and as originally installed, were provided with a preheat section to recover the heat loss of subcooling of the condensate. A hydraulic jet air-ejector system was installed for air removal. In the modernization work, which was carried on simultaneously with the installation of the high-pressure capacity, an open-type deaerating heater was installed in the hot wells for deaerating the condensate and makeup water, as well as for recovering the heat loss in subcooling the condensate. The preheat section was converted into additional condenser service, and the entire condenser was retubed and the tube arrangement redesigned to allow for efficient distribution of steam throughout the condenser. This was accomplished by increased and improved steam laning. Summer peak capacities of each unit have been increased from about 31,000 kw to full generator capacity by these changes, and, even under peak river-temperature conditions, excellent vacuum conditions have resulted.

Further Increases at Columbia

In the depression years the increase in use of air conditioning, fans, refrigeration, and other home appliances had developed new summer loads to a point where summer and winter peaks were substantially equal. This tended to eliminate the summer maintenance period and made greater reserves necessary. To meet this situation and to provide for the continued system-load growth the third unit at Columbia was made necessary.

The unit is a 65,000-kw, 1,800 rpm, hydrogen-cooled condensing-type turbine. It was not felt to be economical to install a superimposed unit at this station due to the high temperature and pressure of operation of the original units.

Two 350,000 pounds-per-hour steam generating units, operating at 675 pounds per square inch, and 910 degrees Fahrenheit supply steam to the unit. A crossover through a desuperheater connects the new steam header to the 600 pounds-per-square-inch, 725 degrees Fahrenheit original plant header. The new boilers are essentially duplicates of West End steam generating units.

The West End and Millers Ford units were put in service during 1937. The Columbia unit was finished in 1938.

Ohio River Flood

About the middle of January 1937, flood waters were rising in the Ohio River. By the 21st of the month, it was evident that a flood of unprecedented magnitude might occur. Construction crews at work on the installation of the new units at Columbia and West End stations, together with plant maintenance crews of the Cincinnati Gas and Electric Company, were immediately put to work on emergency floodproofing of the stations. This work consisted in bulkheading doors and windows, providing additional pumps to remove seepage into the stations and, as the water rose higher, in the temporary location of station power-auxiliary switching and transformer equipment.

As the flood waters rose, difficulty too was experienced in handling coal at both plants. Despite the tremendous effort to maintain service, the stations were forced out of service when the river rose to a point where it was no longer possible to keep the water out. Columbia station was flooded when the water rose to 68.9 feet which was 4.7 feet above the greatest previous flood, which occurred in 1884. West End station remained in service until the river rose to 78.3 feet or 7.2 feet above the 1884 flood. The ultimate rise was to a level of 73.8 feet at Columbia station and 79.99 feet at West End station.

Before the flood had reached its crest work was started on designs for floodproofing the stations. The work of floodproofing was carried along with the completion of Unit No. 5 at West End station, and Unit No. 3 at Columbia station. The floor and wall structures were reinforced to withstand the greater hydrostatic head. Auxiliary switch rooms were removed to high levels. Means of handling coal during high water were added. Auxiliary flood pumps were installed. Power and control cables were raised to levels above the floodproofing level or replaced with waterproof cable. Where normal operations required doors or openings below the floodproofing level, marine type, bulkhead doors were installed so that they could be sealed during floods. At the time of the flood, the substructure for Unit No. 3 had not been long in progress. It was possible to redesign the substructure for the new design level, and this was done immediately.

The new design level for flood at West End station is now 7.4 feet above the crest of the 1937 flood, and for Columbia station the levels above that flood are 7.4 feet for Units Nos. 1 and 2, and 9.4 feet for the new Unit No. 3.

During the flood, the great value of interconnection was demonstrated. No capacity was available at the Cincinnati stations from January 25 to February 1. At no time were any essential loads disconnected. Power was delivered to Cincinnati from Dayton, and over the Indiana interconnections.

Current Program

In the Dayton area, the need for new capacity continued. Early in 1939, Unit No. 8, a duplicate of Unit No. 7, was started at Millers Ford station. The installation was recently completed. The capacity of Millers Ford station is now 170,000 kw.

In anticipation of increased load due to the development of armament loads, a program of increase in capacity is again in progress. At Millers Ford station, Unit No. 2, a 12,500-kw unit will be removed. With modern condensers and changes in steam extraction, it is possible to replace this unit with a modern and more efficient 30,000-kw unit. At Columbia station, Unit No. 4, a 65,000-kw, hydrogen-cooled unit, a duplicate of Unit No. 3, is under construction.

When this program is complete, the capacity of the load-center plants will be, at Millers Ford, 187,500 kw, and at West End, 180,000 kw. The total capacity in the system will then be 623,500 kw.

Interconnections

The Integrated System

The first interconnection between companies which later formed a part of the Columbia system was installed in 1913. This interconnection was between Plum Street station in Cincinnati and the Newport station of the company serving the Kentucky suburbs. The second interconnection was made in 1923 with the Dayton Power and Light Company which was not then a part of the Columbia system. The Cincinnati company was in need of capacity and had contracts with the Dayton company, which resulted in the installation of Unit No. 5 at Millers Ford station so that excess capacity there could be used by the Cincinnati company until the Columbia units could be placed in service. To deliver the capacity to Cincinnati, the systems were interconnected by two 66-kv circuits from Millers Ford station to Elmwood substation in Cincinnati. These circuits followed the general course of the Miami River from Cincinnati to Millers Ford station. The lines were completed in 1923.

With the acquisition of the Dayton properties the two companies with their interconnections became the present integrated electrical system of the Columbia Gas and Electric Corporation.

Interconnection With Other Systems

In 1924 the first interconnection with an outside system was made. This, a 66-kv circuit, was run from a new substation at Hamilton, Ohio, on the Cincinnati system, to the Indiana state line where it joined a circuit from Connersville, Indiana, on the system of the Public Service Company of Indiana.

A few years later the Indiana company was in further need of capacity. The additional capacity was delivered over the 132-kv circuit constructed in 1927, from Columbia station of the Cincinnati company to the Indiana company's Lenore substation near Indianapolis.

At the same time companies adjoining the Dayton company were in need of capacity. To supply the Ohio Edison Company at Springfield, a 66-kv circuit was built from Millers Ford to their Mad River station. A double-circuit line, built for 66 kv, but operated at 33 kv, was built from Millers Ford to the substation of the Greenville Power and Light Company at Covington, Ohio, to meet the needs of that company. The Dayton company's interconnections were completed in 1929.

In 1929, the decision was made to interconnect the Cincinnati company with the Louisville Gas and Electric Company. After satisfactory negotiations had been completed, work was started on the 132-kv line. This interconnection was completed in 1930. The operation of this circuit has been of great value to both companies. Virtually continuous use is made of the circuit for transfer of economy energy between systems. During light-load periods dump hydro-generated energy is delivered from Louisville to Cincinnati and during heavy load periods and at times when the hydro plant is out, low-cost Cincinnati steam-generated energy displaces generation in the Louisville system's higher cost peak-load plants.

For some time, there had been under discussion interconnection of this system and the American Gas and Electric system. An agreement was recently reached to construct a 132-kv circuit from Trenton substation of the Cincinnati company to Delaware substation of the Indiana General Service Company at Muncie, Indiana. This interconnection is now under construction.

The principal purposes of this interconnection are:

1. Reduction in required reserve generating capacity.
2. Insurance to service if a major source of supply is lost.
3. Savings and profits resulting from trading in economy energy.
4. Possibilities of staggering construction of generating capacity by short-time purchases and sales of capacity.

In all, three 132-kv circuits with a capacity of approximately 60,000 kva each will interconnect the Cincinnati system with the systems of adjacent states. The two Indiana systems in turn connect to the great interconnected systems of this region. A second circuit can be installed on the double-circuit steel tower lines to the Indiana companies. With completion of present construction, the interconnection capacity of the Cincinnati system at 132 kv will be approximately 180,000 kva and by addition of the second circuit on the two tower lines this capacity can be increased to 300,000 kva. In addition the capacity in the 66-kv transmission between the Cincinnati and Dayton groups makes capacity of either system available to the other.

Transmission and Substations

EARLY DEVELOPMENTS

When West End and Millers Ford stations were first started, it became necessary to develop transmission systems to connect the new stations to the existing stations and substations.

In the Cincinnati area, the existing Plum Street and Newport stations generated at 4,500 volts. To interconnect these stations, transformers at both stations, and two circuits operating at 11,000 volts had been installed in 1913. Similarly, circuits had been constructed to several substations in the suburban areas. These circuits provided a nucleus for a transmission system out of West End station. As 13.2 kv was rapidly becoming the standard voltage for generation and the existing transmission could be operated at that voltage it was selected for the new generators.

The new conduit systems for the transmission were constructed in 1916 and 1917. At that time, this was a very modern and most elaborate system. Ducts were installed from West End station to five substations. The trench length of the system was approximately 100,000 feet. Of this 8,000 feet were in the flood area near the station. At the time it was thought that this portion of the system must be watertight. The manholes had a heavy outer lid and an inner lid, with a gasket and clamping bars, to prevent the entrance of surface water. Also it was necessary to cross under many railroad tracks, gas and water mains. This required an unusual depth and strength of structure. The average trench depth here was 16 feet. The manholes were also of unusual depth, one manhole had a depth of 32 feet. The concrete duct system itself was steel reinforced and in section area approximately 250 per cent that of a modern system with an equal number of ducts. This transmission system continued to develop until 1923 in the form of radial feeders to substations.

In the Dayton system a new duct system was built and cables for operation at 6,600 volts were installed from Millers Ford station to Third and Fourth Street stations. This system continued to develop at this voltage for several years, but it soon was evident that a higher voltage would be more economical. The first step in this direction was made to increase the capacity of the circuits to Third Street station. Autotransformers were installed at Millers Ford and Third Street stations, and the operating voltage of the cables was changed from 6,600 volts to 12,000 volts.

To supply territory surrounding Dayton and Cincinnati 33-kv transmission systems were developed. In the Dayton area, this transmission was built in the form of a belt line around the city with radial taps to the surrounding area.

THE 66-KV SYSTEM

In 1924 and 1925 while Columbia station was under construction extensive additions were being made to the Cincinnati transmission system and substations. To deliver the power to the Cincinnati area, two double-circuit, 66-kv steel tower transmission lines were constructed from Columbia station to a new 66-kv switching station, Hartwell Terminal substation, to the north of the city. Two new step-down substations, Mitchell Avenue and Oakley, were erected. The 66-kv Dayton-Cincinnati interconnection circuits were brought into the Hartwell Terminal substation. The existing 66-kv circuits were used to supply Elmwood substation from Hartwell. A double-circuit steel tower line was built from the terminal substation to each of the new Oakley and Mitchell Avenue substations. A 66-kv substation was built at Trenton to supply the load in the Middletown and Franklin areas.

OPERATING EXPERIENCES

The 66-kv transmission plan as originally conceived intended that one pair of the Columbia-Hartwell circuits should be brought into each bus section at Hartwell substation and the busses there were to be operated with the bus tie open. It was intended that ultimately two 66-kv circuits from Hartwell through substations would tie to West End station. Without these ties in service it was found that the transmission from the step-down stations to West End would not satisfactorily divide load if the bus sections at Hartwell were operated with the bus-tie breaker open. The system was then operated with the busses at Hartwell tied together normally.

The development of the 66-kv system marked a transition in the Cincinnati system operation. Heretofore, the system had cable transmission as the main supply to load. With the new 66-kv transmission new protection problems for faults on the 66-kv system arose. Lightning storms became a major concern. While it had not yet become evident, a system-stability problem had been created. In the Cincinnati system two short circuits occurred which influenced the design of the system transmission and substations. In 1930 a bus fault caused by a circuit-breaker failure at West End station destroyed a length of bus supplying five switch positions. In 1932 a lightning-arrester failure caused a three-phase short circuit of such duration that system instability resulted. The loss of load at Columbia station during the fault caused the turbines to be tripped by their overspeed devices. It was necessary to drop load in Cincinnati to avoid complete loss of load at West End station.

Stability studies were made to determine the most economical solution to this problem. One of the principal causes of the instability was the large portion of the system load transmitted from Columbia to the Cincinnati substations. By reducing the proportion of load carried at Columbia it was possible for the existing protective equipment to clear 66-kv faults in time to prevent instability. This restriction is no longer necessary as the present transmission system is adequate to maintain stability under all normal conditions.

REMEDIAL MEASURES

The original bus at Columbia station was a separated phase structure and was provided with ground-fault bus protection. Following the bus fault at West End similar protection was applied at that station and the principal 13.2-kv substations. Also, the circuit breakers at West End station were equipped with an improved type of contact. With the development of the De-ion grid the circuit breakers were again rebuilt. De-ion grids were also installed in circuit breakers at the principal 66-kv and 13.2-kv substations.

Early operating experience had indicated the need for protective equipment which would quickly disconnect short circuits from the system. To this end transmission circuits were arranged in pairs and balanced protection applied to all principal circuits. With the growth of the system it became more evident that the system as a whole should be fundamentally designed to prevent long outages to any major portion of the system.

An opportunity to attack this problem came with the addition of Unit No. 3 at

Columbia station. It was necessary to provide additional transmission to the 66-kv system and also substations to step down to the 13.2-kv load. It was desired that the new transmission should accomplish three things.

1. Increase capacity out of Columbia station.
2. Solve the stability problem.
3. Provide greater reliability to the 66-kv system as a whole.

Among the hazards to service were certain busses where short circuits could disrupt the system. Also, certain important busses were tied by one breaker, where, should a short circuit occur, both busses would be lost.

The solution finally adopted had two fundamentals. (1) The 66-kv transmission would be developed into two halves as had been originally intended. (2) When the two halves were tied together at generating stations or at substations the bus tie would be through two circuit breakers in series. Employment of these principles allowed confinement of major bus faults to one-half of the 66-kv system and confinement of bus outages to one section only.

One of the first projects in this direction was to rebuild Hartwell substation to reduce the hazard existing there. As it was then operated, a fault on the bus could completely separate all three generating stations. The station was rearranged into two structures with wide physical separation. The steel structures and circuit breakers were insulated from ground- and bus-fault protection applied to each bus structure and the bus-tie section separately.

A development of the original 66-kv transmission plan was started. The present development together with authorized construction now in progress is shown in figure 3. The plan includes the construction of two step-down transformer installations at Front Street substation located at West End station. The substation will consist of two physically separate structures. The 13.2-kv side of each transformer is to be tied to separate busses at West End station. As planned each structure will have two circuits, one circuit to Columbia station, the other to a suburban Cincinnati 66-kv substation. The first bus now complete is tied by a 66-kv cable circuit to Oakley substation. The circuit, eight miles in length, has a capacity of 60,000 kva. It consists of three single-conductor oil-filled cables. While only one cable circuit was installed the duct system was built for two circuits. It was intended that the spare duct be used for transmission from the ultimate second section at Front Street substation to the 66-kv system out of Hartwell substation.

A double-circuit steel tower transmission line connects Front Street substation with Columbia station. In the initial installation one circuit with a capacity of 60,000 kva was installed. Work to be done next year will complete Front Street substation, and the second transmission circuit from there to Columbia station.

The 13.2-kv terminals of the step-down banks terminate in the new switch house at West End station. The new building was constructed with a vertical fire wall separating the two bus sections on each two floors. One floor houses the two feeder sections, the other the two sections of the new equalizer bus. Each bus room has one outside wall in which are installed explosion-type windows which automatically open in the event an explosion should occur. Each bus section in the old and new switch houses ties through reactors to the equalizer sections. These ties have circuit breakers at both ends and are equipped with differential protection. The busses are normally tied only through the equalizer busses. The new bus sections are of metal-clad construction and bus-fault protection applied throughout. The same double bus-tie circuit-breaker arrangement used at Hartwell substation was employed.

A fire wall was built to divide the old switch house into two bus rooms and each room equipped for explosion-pressure relief. All the old and new bus rooms were equipped with emergency exhaust fans.

Along with the installation of Unit No. 7 at Millers Ford a program of modernization of the switch galleries was started. The old switches and busses were in concrete cells. They were designed for operation at 6,600 volts. At this time it was evident that considerable gain in transmission capacity to the Dayton substations could be made available if all were changed to operation at 12 kv. To supply these circuits a portion of the old 6,600-volt bus was rebuilt for 12-kv operation. The new structures were entirely metal enclosed and provided with fault-bus protection. The new generator was purchased for operation at 12 kv. Units No. 5 and No. 6 were reconnected for 12-kv operation. These three units were brought into the new 12-kv section. All circuit breakers were equipped with Deion grids.

The principal 12-kv substations at Dayton are West Side and Fourth Street. Previous to this change the original circuit breakers at West Side substation had been replaced by breakers of modern design. With the change to 12-kv operation the circuit breakers at Fourth Street were replaced by new and modern equipment.

PROJECTS DUE TO FLOOD

The 1937 flood put several substations in the Cincinnati system out of service. The principal outages to customers not in the flooded area occurred due to the loss of one of the Kentucky substations. This substation was replaced by two new substations built on high ground. Other substations were moved to higher ground or the equipment raised to higher levels. Construction of Front Street substation was under way but it was possible to alter the design to meet the new flood level requirements.

A government project to protect the Mill Creek Valley from back water of Ohio River floods is soon to be started. This is a barrier dam project. Pumps installed there must pump the flow of Mill Creek plus some sewage over the dam during floods in the Ohio River. The pump load, a maximum of approximately 50,000 kw, will be supplied by two 66-kv circuits. A steel tower line will be built from Front Street substation through the dam to Mitchell Avenue substation. These are two of the most reliable busses in the 66-kv system. Mitchell Avenue and Front Street are in the heart of this system. Three generating stations and two of the major interconnections connect directly to this system. Capacity in Indiana would not be affected by Ohio River floods and the Columbia system stations are flood-proofed to a level above that of the barrier dam. The dam is thus assured two very reliable power sources.

TRANSMISSION CHANGES AT DAYTON

At Wright Field the government proposes to install aeronautical test equipment which will increase the load there to 50,000 kw. To supply this load extensions are being made to the 66-kv system. A second 25,000-kva bank was installed at Millers Ford station. A new 66-kv substation is being constructed at Overlook substation. This substation will be supplied by two 66-kv circuits from Millers Ford station. Wright Field will have two sources of supply at 66 kv, one direct from Overlook substation, the other a tap off the Springfield interconnection.

The principle of tying the busses through two circuit breakers was carried out at Millers Ford and Overlook 66-kv substations. The protection is slightly different in that the tie section and circuit breakers are in the line protection.

Along with the installation of the new unit at Millers Ford station further extensions are being made to the metal-clad 12-kv bus structures. During the next year the work of completely replacing the old bus structures with a metal-clad 12-kv protected bus will be finished.

Conclusion

The principle of developing generating stations of approximately equal size and efficiency in several locations near load centers has proved highly satisfactory in the operation of this system.

The advantages of interconnection have been recognized in this system as far back as 1913 and it is the intent to continue to develop interconnection to its full usefulness.

The short-circuit protection of major busses and fire-wall provisions in stations and substations have become standard practice. In addition water spray or carbon dioxide fire extinguishing systems are applied to all major equipment.

Short-Wave Diathermy Apparatus and Frequency-Control Possibilities

C. K. GIERINGER
ASSOCIATE AIEE

THE general technique of applying short-wave diathermy has become firmly entrenched in the therapeutic repertoire of the medical profession during the past eight years. The clinical effectiveness of this particular physical treatment, along with the commercial development of apparatus suitable for applying this form of energy at an economical cost, has given it wide usage. In spite of the general acceptance of short-wave diathermy in medicine there seems to be no universally accepted theory regarding the action of the electrical fields or currents in the body tissues themselves. In this country the most widely held theory is that the heating effects created in the tissues by the currents account for all the therapeutical results.[1,2] In Europe there is a school of physicians which holds that athermic treatments are clinically effective.[3]

Long-wave diathermy (contrasted with short-wave diathermy) employing frequencies of the order of 1,000,000 cycles per second has been known and used by doctors for the past 40 years. In this technique the high-frequency currents are applied to human tissue through metal electrodes in direct contact with the patient. The heat generated in the tissues is determined by the length of the treatment, t, the current, I, flowing through them, and their effective resistance, R, as defined by $Q = I^2Rt$. The deep tissues are heated as well as the superficial ones. From the patient's standpoint, the treatment tolerance is determined by the highest-created sensible temperature. Because the skin has a greater resistance than other tissues of the body and is the seat of nerve terminals sensitive to heat, the energy introduced in the patient is largely determined by the heating of the skin. Average healthy adults can tolerate approximately 100 milliamperes per square inch.

Applicators

With the advent of short-wave diathermy apparatus, the energy could be conveniently applied capacitively through insulated electrodes or applicators. The higher frequencies from 10,000,000 to 50,000,000 cycles per second permit the electrodes to be insulated and either placed directly on the patient or spaced a few, or even several, inches away. Furthermore, satisfactory treatment levels of energy do not cause excessive voltages between the patient and the electrodes.

Capacitive applicators have become known to the medical profession as of two different types, pads or cuffs, and spaced-plate applicators (figure 1). Pad or cuff applicators are supported by the patient and may be placed either directly against the patient or separated from him by layers of felt or toweling. These applicators are used at any of the frequencies from 10,000,000 to 50,000,000 cycles per second. Spaced-plate applicators are supported on arms and separated from the patient by air. Spacings up to about six inches are used. The generators for these applicators oscillate in the higher frequency ranges above 25,000,000 cycles per second in order to keep the voltage gradients within safe operable limits.

With short-wave diathermy machines it also became possible to apply energy electromagnetically to human tissue.[4] This is accomplished by wrapping an insulated cable of convenient length and diameter around the part to be treated and passing high-frequency current through the cable. The field set up by the current induces eddy currents within the tissues. An advantage of this method of treatment is that the deeper-lying tissues, having lower resistance than the skin, are heated proportionately more than the more highly resistant skin tissues. Fixed coil configurations mounted in air-spaced bakelite covers, called drums or disks, and fastened to convenient adjustable arms have proved a very flexible, safe, and convenient method of applying treatment energy (figure 2).

Generator

The short-wave diathermy generator consists essentially of a high-frequency, self-excited oscillator circuit using suitable vacuum tubes and being either self-rectified or using a rectified power supply. Most of the models marketed to the medical profession have a maximum output ranging from 200 watts to 600 watts. The patient circuit may be directly, electrostatically, or magnetically coupled. Depending on the type of coupling, the power is controlled in several ways. There may be a variable reactance (usually a capacitor) in the patient circuit; the input energy to the oscillating tank circuit may be controlled; or the coupling to the patient circuit may be varied. Many times a combination of these is used. The relative power output, furthermore, may be indicated either by a radio-frequency ammeter in the patient circuit, or by a milliammeter reading the input plate current to the tubes, or by a differential milliammeter reading the subtractive difference between the average plate and the average grid currents taken by the tubes, or by an auxiliary radio-frequency wattmeter circuit.[5]

Figure 3 shows the circuit diagram of a typical short-wave diathermy machine in which the patient circuit is inductively coupled and power output is controlled by a variable capacitor in the patient circuit. The power indicator is coupled magnetically to a tapped coil which carries average plate and grid current in such a manner that under idling conditions, i.e., no power expended in the patient circuit, the net voltage impressed on the indicator is zero. When the unit is fully loaded the instrument reads full scale. It is realized, of course, that in such an oscillator the input plate current consists of half-wave pulses of the power frequency. The meter then responds to the a-c components in the plate and grid currents. Linked magnetically to this metering circuit is an armature set to operate contacts when the load exceeds a predetermined value. The opening of the contacts inserts in the circuit cathode bias which automatically reduces the input into the tube and thus prevents damage should the difference in plate and grid current exceed a predetermined value.

Patient-Circuit Impedance

The external patient-circuit impedance varies over an exceedingly wide range. Not only does it vary from one treatment condition to the next, but it will vary even

B. Spaced-plate treatment of respiratory tract

several hundred per cent with movements of the patient during the course of the treatment. It is this characteristic which sharply differentiates short-wave diathermy engineering from conventional radio transmitting circuit practice. It is necessary in the design of the generator and applicators that adequate treatment power always be available for any accepted technique of treating. The reactance of the external patient circuit may be capacitive, inductive, or zero. In turn, the applicators, the length of the applicator leads, their proximity to each other, and the frequency, affect the value of the reactance presented to the generator. In general, the reactance of the path in the patient himself is negligible compared with the reactance of the electrode patient path. This results from the high average dielectric constant of human tissue, approximately 78 for all except fat which is about 13. Where capacitive or magnetic coupling and a variable capacitor to control power is used, the patient-circuit constants must be so chosen that the range of reactances of the external circuit can be adequately compensated to allow sufficient energy to flow.

The resistance of the external circuit is determined by the frequency, the type of applicator, and its configuration. The actual path within the patient, however, influences the resistance considerably. For example, a pair of pads placed on the front and back of the chest under certain conditions would present seven ohms resistance to the generator. If the pads were then placed with the same spacing, lead arrangement, etc., under the foot and on the knee, the resistance would be approximately 50 ohms. Table I shows typical values of patient-circuit resistances encountered in practice.

The conventional manufacturing practice has been to use fixed coupling of such an amount that satisfactory treatment energy can be transferred to the patient under conditions having the greatest resistance. This procedure has simplified the control of the generator. It is obvious that for treatment conditions having low resistances the generator will be overcoupled. In such situations, with a change in patient-circuit reactance, the reflection of the patient-circuit impedance in the oscillator may cause considerable frequency shift (15 per cent or more). Furthermore, excessive oscillator loading may occur unless the unit is equipped with satisfactory automatic circuit protection.

Interference

It is generally recognized that short-wave diathermy machines may interfere with radio communications.[6] The possible and alleged interference caused by these machines has been and is being studied from many angles by the groups primarily interested, The Federal Communications Commission, The American Medical Association, the Physical Therapy Manufacturers' Group, communication interests, The National Electrical Manufacturers' Association, and The Radio Manufacturers' Association.[6,7,8,9,10] To date no definite agreement has been reached by all the interested parties. It is generally agreed, however, that the interference at distances greater than a few hundred feet is caused by radiation primarily from the electrodes, patient, and associated leads. Reber and Richardson[6] have shown the field strength under actual treatment conditions to be given by $v=v_0/d^k$ where v is the field strength of the signal in microvolts per meter, v_0 is field strength at a distance of one mile, d is distance in miles from the source, and k ranges from two to three. v_0 may vary from 1 to 50 microvolts per meter. When the machine is used without a dissipative load, i.e., no patient, v_0 may be several hundred microvolts per meter. They also have reported the average diathermy signal to be of the order of one microvolt per meter.[7,8] Other tests have been conducted and the results given much publicity, but the machines

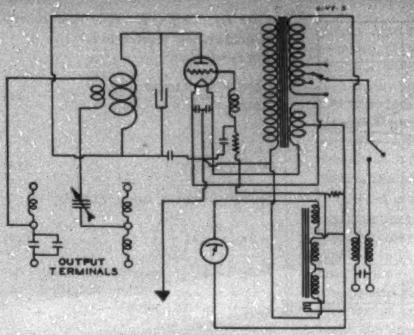

Figure 3. Single-dial-controlled, tuned-plate tuned-grid self-rectifying diathermy circuit. Note the three pairs of terminals in the patient circuit

were not treating under practical conditions. Instead, they were operating without a dissipative patient load in which signals had been detected over long distances.[11] It is held by some that the technical solution of providing adequate shielding for treatment rooms would not prove a practical economical one. It does appear, however, that standards regarding the following points may be adopted.

1. Nominal frequencies to be used.
2. Type of emission.
3. Maximum power output.
4. Amount of harmonic radiation.
5. Effective shielding of internal circuit.
6. Elimination of radiation from power supply.
7 Frequency stability.

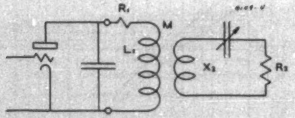

Figure 4. High-frequency portion of diathermy circuit

On the first six of the above points all the interested groups are in general agreement that a technically and economically satisfactory solution could be adopted.

Frequency Stability

The problem of frequency stability, on the other hand, is one of the most important of the seven, since the degree of stability attained will directly affect the cost and service requirements to the doctor, and indirectly affect the cost of adequate medical attention to the public. Because of the expense and complication of master-controlled oscillator circuits, the following analysis was undertaken to determine the degree of frequency stability possible with simple, conventional, self-excited, oscillator circuits.

Figure 4 shows the oscillator tank circuit and coupled patient circuit. Figure 5 shows the equivalence of this circuit.

$$Z_{00}=R_1+j\omega L_1+\frac{\omega^2M^2}{Z_2} \tag{1}$$

$$=R_1+\frac{\omega^2M^2R_2}{R_2^2+X_2^2}+j\omega(L_1+\Delta L) \tag{2}$$

where

$$\Delta L=\frac{-\omega^2M^2X_2}{R_2^2+X_2^2} \tag{3}$$

is the reflected inductance in the tank circuit and

$$R_R=\frac{\omega^2M^2R_2}{R_2^2+X_2^2} \tag{4}$$

is the reflected resistance in the tank circuit.

For a small change, ΔL, in L_1, the percentage change in resonant frequency is given by

$$\frac{\Delta f}{f}=\frac{1}{2}\frac{\Delta L}{L_1} \tag{5}$$

Substituting (3) in (5)

$$\frac{\Delta f}{f}=\frac{1}{2}\frac{\omega^2M^2X_2}{\omega L_1(R_2^2+X_2^2)} \tag{6}$$

and will be plus or minus, depending on the value of X_2.

The output power in the patient circuit is

$$I_T^2R_R=I_T^2\frac{\omega^2M^2R_2}{R_2^2+X_2^2} \tag{7}$$

It is to be noted from figure 6 that, as the patient circuit is tuned toward resonance from the inductive reactance side, the frequency deviation increases the oscillator frequency. At low values of R_2, as the tuning capacitor is further decreased in capacity below the value $X_2=R_2$, the frequency goes down, decreasing X_2 further, which decreases the frequency more, and so on until the oscillator stabilizes itself by operating at a negative-frequency deviation with the patient circuit having capacitive reactance. The output under such stabilized conditions may be more or less than the output under the conditions just before the frequency changed rapidly. For fixed coupling it is obvious from figure 6 that for low values of R_2 it may be impossible to reflect enough resistance into the tank coil to obtain maximum output from the oscillator. Practical use is made of this property in diathermy apparatus. The generators are critically coupled for the high-resistance loads and the above frequency instability is adapted to prevent overload of the tube when low-resistance paths are treated.

Maximum Frequency Deviation for Fixed Maximum Output Power

Assume that a generator is arranged with a fixed magnetic coupling between the tank circuit and the patient circuit. The problem is to determine the maximum frequency deviation for any patient-circuit resistance with the limitation that the maximum power dissipated in the coupled circuit under any condition will be fixed. It is understood that the power in the output circuit is controlled by varying its reactance. The problem is solved logically under three headings, i.e., when the resistance in the patient circuit is critically coupled, when the maximum frequency deviation occurs below the fixed output value, and when the maximum frequency deviation occurs at the fixed maximum output.

$$\omega^2M^2=R_LR_c \tag{8}$$

where R_c is the critical secondary resistance such that $R_R=R_L$, the reflected resistance, just loads the oscillator to full load when $X_2=0$.

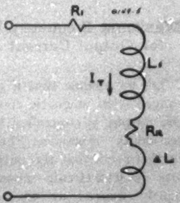

Figure 5. Equivalent circuit shows frequency variation is dependent on ΔL

Let

$$R_2 = kR_c$$

k may vary theoretically from 0 to ∞.

Case I. Critical coupling. $k=1$.

It is seen that $\Delta f/f$ is a maximum at $X_2 = R_2 = R_c$ and from (6) that

$$\frac{\Delta f}{f} = \frac{1}{4Q} \tag{9}$$

where Q is $\omega L_1/R_L$.

Case II. Maximum frequency deviation below maximum output. $k \geqq 0.5$.

In general $\Delta f/f$ is maximum when $X_2 = R_2 = kR_c$. For certain values of k, X_2 will be greater than kR_c, since its value is determined by the maximum load on the oscillator.

Let the reflected resistance term of (4) equal R_L. Solving for X_2 to satisfy this condition,

$$X_2 = R_c\sqrt{k(1-k)} \tag{10}$$

which determines the value of X_2 where maximum frequency deviation occurs, X_2 being limited by the output of the oscillator. $X_2 = kR_c$ determines where maximum frequency deviation occurs before the oscillator is fully loaded. At $k = 0.5$ both of these conditions are satisfied. For $k=0.5$,

$$\frac{\Delta f}{f} = \frac{1}{k}\,\frac{1}{4Q} \tag{11}$$

$$= \frac{1}{k} \quad \text{[maximum frequency deviation for critical coupling]}$$

Case III. Maximum frequency deviation at the maximum output. $k \leqq 0.5$.

Substituting (10) in (6), then

$$\frac{\Delta f}{f} = \frac{1}{4Q}\,2\sqrt{\frac{1}{k}-1} \tag{12}$$

$$= 2\sqrt{\frac{1}{k}-1} \quad \text{[maximum frequency deviation for critical coupling]}$$

Figure 7 shows that it is possible for the frequency to vary 20 times the critical coupled deviation when $k=0.01$. If the maximum power output is reduced 50 per cent the possible frequency variation at $k=0.01$ is reduced only 25 per cent.

Maximum Frequency Deviation for Output Current Limited

Let us assume that a generator is arranged with magnetic coupling and that the output is controlled by varying the secondary reactance. Let us assume, furthermore, that the output current for any patient-circuit impedance is arbitrarily limited at the current which would flow at the critically coupled condition for the given patient-circuit resistance. Then, this analysis, too, is divided into three parts, i.e., the critical coupled condition, the condition where the current limitation determines the maximum frequency deviation, and the condition where the current limitation has no effect in determining the maximum frequency deviation.

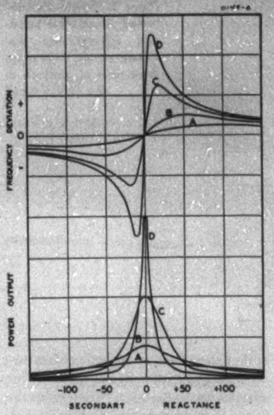

Figure 6. Variation of frequency and power with secondary reactance X_2

A—R_2 100 ohms
B—R_2 50 ohms
C—R_2 20 ohms
D—R_2 10 ohms

Case I. Critical coupled. $k=1$.

Here $X_2 = kR_2 = R_c$ and

$$I_2 = \frac{\omega M I_T}{\sqrt{2}R_c} = \frac{I_c}{\sqrt{2}} \tag{13}$$

and

$$\frac{\Delta f}{f} = \frac{1}{4Q} \tag{14}$$

Case II. $k \geqq \sqrt{2}$.

The value of k where I_2 just equals I_c and at the same time

$$X_2 = kR_c$$

is

$$\frac{I_2}{I_c} = \frac{1}{\sqrt{2k}}$$

and

$$k = \sqrt{2} \tag{15}$$

Therefore for $k \geqq \sqrt{2}$

$$\frac{\Delta f}{f} = \frac{1}{k}\left(\frac{1}{4Q}\right) \tag{16}$$

Case III. $k \leqq \sqrt{2}$. I_2 is now considered deliberately limited to $I_2 = I_c$.

For $I_2 = I_c$ then

$$\frac{\omega^2 M^2 I_T{}^2}{X_2{}^2 + k^2 R_c{}^2} = \frac{\omega^2 M^2 I_T{}^2}{R_c{}^2} \tag{17}$$

and

$$X_2 = R_c\sqrt{1-k^2} \tag{18}$$

Substituting (18) and (8) in (6)

$$\frac{\Delta f}{f} = 2\sqrt{1-k^2}\left(\frac{1}{4Q}\right) \tag{19}$$

$$= 2\sqrt{1-k^2} \quad \text{[maximum frequency deviation at critical coupling]}$$

It is seen from figure 8 that when X_2 in the patient circuit is limited so that I_2 does not exceed I_c, the maximum frequency deviation will not exceed double the deviation possible at critical coupling. A reduction of ten per cent in the maximum output current reduces the possible frequency variation approximately 20 per cent at $k=0.01$. The output is inversely proportional for k greater than one and directly proportional for k less than one.

Tank-Circuit Efficiency

In the above discussion it is to be remembered that the Q considered is that due to reflected secondary resistance in the tank circuit. The operating Q of the

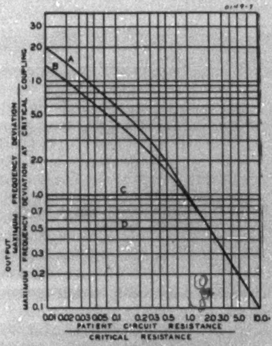

Figure 7. Possible frequency departure and power output versus patient-circuit resistance for fixed coupling and limited output conditions

A—Frequency departure for 100 per cent output
B—Frequency departure for 50 per cent output
C—Output limited to 100 per cent
D—Output limited to 50 per cent

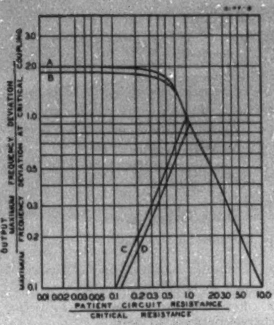

Figure 8. Possible frequency departure and power output versus patient-circuit resistance for limited output current

A—Frequency departure for 100 per cent I_c
B—Frequency departure for 90 per cent I_c
C—Power output for 100 per cent I_c
D—Power output for 90 per cent I_c

tank circuit, however, is determined by the reflected resistance, the resistance of the tank coil and condenser, and the equivalent resistance representing the grid-circuit losses. In a self-excited oscillator the grid-circuit losses vary with the load on the oscillator, being higher at no load than at full load.

The tank-circuit efficiency, η, is given by the ratio of R_L to $R_{F.L.}$

Where

$R_{F.L.}$ is the sum of the resistances enumerated above
$Q_{F.L.}$ is the full-load Q of the tank circuit
$Q_{N.L.}$ is the Q of the tank circuit at the idling condition, i.e., no power flow in the patient circuit
a is the ratio of the grid-circuit loss at no load to the grid-circuit loss at full load
b is the ratio of grid-circuit loss at full load to the coil loss at full load

In practical oscillating circuits having values of Q over 100 an average value of $\left(\frac{1+b}{1+ab}\right)$ is 0.94.

The tank circuit efficiency, η, is

$$\eta=\left[1-\left(\frac{1+b}{1+ab}\right)\frac{Q_{F.L.}}{Q_{N.L.}}\right]100 \text{ per cent}$$

and the frequency deviation at critical coupling is

$$\frac{\Delta f}{f}=\frac{1}{4Q_{F.L.}}(\eta)$$

In figure 9 it is evident that by using full-load tank circuit Q's of the order of 100 or more it is possible to hold the frequency deviation due to patient-circuit coupling to less than plus or minus 0.2 per cent when the short-wave generator is critically loaded. This amount of circuit stability is attainable with conventional circuits, tubes, and equipment, as currently used in short-wave diathermy apparatus with some sacrifice in maximum attainable power output.

Critical coupling can be obtained for each patient-circuit load by providing variable coupling between tank and patient circuit. Simple instructions to the user of the equipment, insisting on tuning the patient circuit to resonance and using the lowest value of coupling compatible with the power necessary for treatment, could possibly keep the frequency swing, due to the patient-circuit loading, at or near zero. If no control or indicator is on the generator other than a plate-current limiter, it is possible for the frequency to vary as shown in figure 7. An output current limiter arranged to limit current to I_c for any coupling would hold a possible frequency variation, as shown in figure 8, to within twice that of the critical coupled load.

From the foregoing analysis and discussion one can see how the frequency swing of diathermy apparatus may be limited to within 0.25 per cent for any possible patient-circuit condition. Two channels, one in the 10- to 20-megacycle range, the other preferably harmonically related in the 20- to 40-megacycle range, with a slightly greater than the abovementioned frequency variation, should prove adequate from a medical, manufacturing, and commercial standpoint. There can be no doubt that this procedure would reduce the problem of diathermy interference to a negligible amount as compared to the avowed present situation where any given machine is operated on a frequency partly determined by the whim of some manufacturer, and partly by the condition of its use. In the light of radio communication practice the above suggested frequency tolerance seems quite large. However, when it is considered that all short-wave diathermy apparatus may be operated on the allocations suggested above, it would appear that such a solution should stand on its own merits.

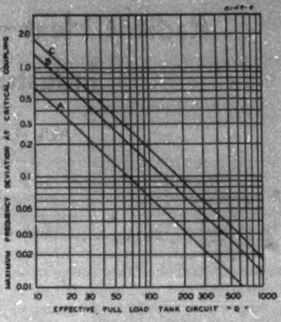

Figure 9. Per cent frequency departure versus effective full-load tank circuit Q

A—Tank circuit efficiency—25 per cent
B—Tank circuit efficiency—50 per cent
C—Tank circuit efficiency—75 per cent

Radiant Heat—a Full-Fledged Industrial Tool

PAUL H. GOODELL
ASSOCIATE AIEE

Introduction

ALTHOUGH the great majority of commercial heat sources deliver an appreciable portion of their energy in the infrared spectrum, most industrial heating processes now rely on heat transfer by convection. With the intermediate heating of the air between the source and the point of useful work, two or more energy transfers result with consequent loss in speed of transfer and efficiency while the available radiant energy is largely converted into convected heat by the heat transfer system before it is usefully employed.

The ability of radiant energy to heat objects apparently without regard to the surrounding air temperature has been known to man since his first exposure to the sun. The wave lengths responsible for this phenomenon have since been found to be those longer than visible radiation and because they are nearest the red end of the spectrum the name infrared or near red has been applied.

Infrared heating differs from other methods of heating primarily in that the energy is delivered directly from the source to the intended work in radiant form. Consequent convection from parts at elevated temperature is then a secondary rather than an intended result.

Temperature Investigation

In convection oven practice heat transfer is directly proportional to the temperature differential between the working surface and the surrounding air. Air movement helps eliminate the insulating influence of gaseous films adjacent to the work and thus directly increases the heat transfer. The rate of temperature rise inherently diminishes as the temperature of the work approaches that of the surrounding air, and when a state of equilibrium is reached no further useful heat transfer is effected. The temperature is also influenced by the mass, conductivity, and specific heat of the material.

In the direct transfer of radiant heat, the rate of temperature rise is directly dependent on the ability of the surface to absorb the energy and the concentration or density of the energy received. Mass, specific heat, and conductivity will affect the temperature rise and the uniformity of temperature within the material being heated. As in convection heating, however, the mean temperature finally attained is solely a matter of equilibrium but in radiant energy practice this occurs when the rate of heat loss is equivalent to the rate of energy input. Air temperature which is then not important in the original heat transfer becomes important because of its influence on losses since the temperature differential is customarily in reverse relation to that for convection practice. This provides inherent advantages for numerous types of applications while on others the heating cycle may be completed well before the equilibrium state is reached thus providing high operating efficiency. Since a knowledge of the heat flow as effected by these influencing factors is fundamentally essential to the design of radiant heat ovens, research studies have been undertaken to determine how known laws of thermodynamics might be suitably applied to radiant heating.

The equipment used for these studies included a 60-kw laboratory oven employing Thermalamp sources capable of providing uniform energy concentrations up to ten watts per square inch. Temperature measurements were made with a special Leeds and Northrup recording potentiometer balancing a thermocouple circuit once every second. Energy measurements were made with a special instrument developed for the purpose comprising a thermocouple and milliammeter circuit employing a black body receiver in an evacuated envelope to avoid convection effects. The test objects were mounted on a conveyor operating through the center of the oven illustrated with the various instruments in figure 1.

Radiation transferred from the source to the work may be diverted into:

1. Useful energy absorbed and conducted through the work.
2. Reflected energy losses due to surface characteristics of the work.
3. Convected energy losses to the surrounding air.
4. Re-radiation as may result due to the elevated temperature.

All tests were made from an initial air temperature of 80 degrees Fahrenheit. Losses by re-radiation were held to a negligible level and consequently not separated from other losses through the use of a test procedure in which the experimental panels were surrounded by surfaces at equivalent or higher temperatures. To further assure accuracy in the determination of constants for verifying theoretical conclusions, the reflected losses were held to a minimum by the use of black surfaces. Convected heat then accounted for the principal losses from the test panels.

With the working surfaces and surrounding air at the same initial temperature in the test procedure employed, the *initial* rate of temperature rise would be dependent only upon the radiant energy absorbed per unit area, specific heat, and mass of the material since the convected losses are momentarily negligible.

The heat in British thermal units necessary to raise any thin object through

Figure 1. Experimental equipment for radiant heat investigations

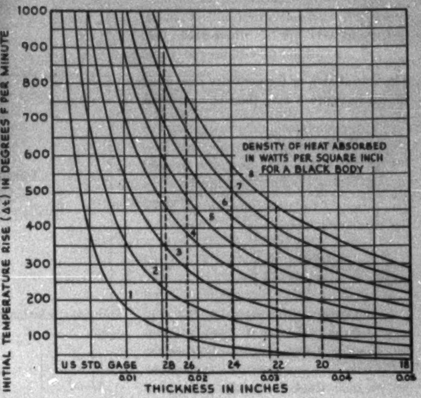

Figure 2. Initial rate of temperature rise for thin steel panels at various energy absorption rates

Δt degrees Fahrenheit per minute is then given by

$$Q = sm\Delta t \tag{1}$$

where s is the specific heat, m the mass, and Q the British thermal units per minute. As 3,413 Btu are equivalent to one kilowatt-hour, one British thermal unit per minute equals 17.58 watts. The relation between watts and British thermal units per minute is then

$$\text{watts} = 17.58Q = 17.58s(\rho Ad)\Delta t \tag{2}$$

where ρ is the density in pounds per cubic inch, A the area in square inches, and d the thickness in inches. For steel, the equation for watts per square inch as a function of d and Δt becomes

$$w = 0.55d\Delta t \tag{3}$$

For a given set of conditions this relation indicates that the initial rate of temperature rise is directly proportional to the watts per square inch input. This conclusion was confirmed experimentally and figure 2 shows the initial rate of temperature rise which may be expected at various energy absorption rates for thin steel panels with a true black body surface. The initial rate of temperature rise for a nonblack body may then be obtained from the product of the black body temperature rise and its reflection factor for the infrared spectrum. This reflection factor is discussed later in the paper.

These data would also hold for heavier masses except that the surfaces are initially heated more rapidly than would be indicated by the relation of total masses as expressed in (2) and (3). In practice such temperature acceleration would be greatly diminished after the first few seconds of exposure even for thin plates, due to the increasing rate of convection losses which constitute the next phase of this investigation.

In the interest of economy convection losses are held to a minimum in commercial practice. To simulate this condition in the test procedure, draft shields were used to limit air circulation to natural convection. According to Newton's law of cooling, the rate of heat loss is directly proportional to the difference in temperature of the work and the surrounding medium. This is expressed mathematically as:

$$\frac{dt}{d\theta} = k(t - t_a) \qquad \text{where } k < 0 \tag{4}$$

The temperature of the material is represented by t, time in minutes by θ, and air temperature by t_a. Separating the variables and forming the integral

$$\int_{t_0}^{t} \frac{dt}{t - t_a} = \int_0^{\theta} k\,d\theta \tag{5}$$

The limits of integration are determined by the mass cooling from t_0 to a temperature, t, at time θ. Integration of (5) gives

$$\log_e \frac{t - t_a}{t_0 - t_a} = k\theta \tag{6}$$

or solving for t to obtain the theoretical time-temperature cooling curve

$$t = t_a + (t_0 - t_a)e^{k\theta} \qquad \text{where } k < 0 \tag{7}$$

This equation is approximated by experimental data shown in the cooling region of figure 3.

k is most easily determined directly from the differential equation 4 by obtaining two values of $dt/d\theta$ and corresponding values of t from the experimental time-temperature curves, and eliminating t_a.

$$k = \left[\left(\frac{dt}{d\theta}\right)_1 - \left(\frac{dt}{d\theta}\right)_2\right] / (t_1 - t_2) \tag{8}$$

The mean temperature of a thin air film adjacent to the work can now be calculated with more accuracy than experimental measurements will permit. This calculation is made either by the original differential equation 4 or by solving for t_a in (6).

Having established the time-temperature relations for heating and cooling, the combined effect for actual determinations of temperature rise becomes the next objective. If the work were radiated uniformly and no heat losses were present, the rate of temperature rise would be proportional to the energy supplied.

$$\frac{dt}{d\theta} = h \tag{9}$$

h is directly proportional to the watts per square inch and may be expressed as:

$$h = \frac{rw}{17.58s\rho d} \tag{10}$$

where w is the energy received in watts per square inch and r the ratio of watts per square inch absorbed to watts per square inch received.

Since the temperature rise is not a linear function of time because of convection losses, equation 9 must be modified.

$$\frac{dt}{d\theta} = h + k(t - t_a) \qquad \text{where } k < 0 \tag{11}$$

Separating the variables and integrating from temperature t_a when $\theta = 0$ to t at time θ

$$\int_{t_a}^{t} \frac{dt}{h + k(t - t_a)} = \int_0^{\theta} d\theta \tag{12}$$

$$\log_e \frac{h+k(t-t_a)}{h} = k\theta \qquad (13)$$

Solving for t gives the theoretical time-temperature curve for heating:

$$t = t_a + \frac{h}{k}(e^{k\theta}-1) \qquad \text{where } k<0 \quad (14)$$

The initial rate of temperature rise, h, as shown in figure 2 may then be expressed as:

$$h = \frac{k(t-t_a)}{e^{k\theta}-1} \qquad (15)$$

The ratio of h to Δt discussed in (2) gives the absorption factor

$$r = \frac{h}{\Delta t} = 17.58 \frac{s\rho dk}{w}\left[\frac{t-t_a}{e^{k\theta}-1}\right] \qquad (16)$$

A comparison of theoretical and experimental results is shown in figure 3. For this example a heat density of 7.0 watts per square inch was used on a steel panel 0.0174 inch thick having a coating of black polymerizing paint. Substituting the proper values in equation 8, k is found to be -1.342. Calculating h from equation 15, a value of 640 degrees per minute is determined. The theoretical curve obtained from these values, using equations 7 and 14 shows a variation from the experimental results which can no doubt be attributed to temperature variations in the air adjacent to the test panels during the laboratory procedure. At lower heat densities the results show even higher accuracy thus establishing their usefulness for industrial engineering calculations.

The reflection losses may now be obtained from equation 16 by determining the initial rate of temperature rise (Δt) from figure 2. This value is found to be 710 degrees per minute giving an absorption factor of 0.9 or reflection losses amounting to ten per cent.

The amount of energy usefully employed to produce an intended working temperature may now be determined from the ratio of the effective energy required per square inch to attain the temperature, $sm(t-t_a)$, to the total energy absorbed during time, θ, required for the temperature change. This may be expressed in British thermal units as $rw\theta \div 17.58$. Using η for this ratio, the equation becomes

$$\eta = 17.58 sm(t-t_a)/rw\theta \qquad (17)$$

Expressing t as a function of the time by means of equation 13 and substituting

$$\eta = 17.58 \frac{smh}{krw}\left[\frac{e^{k\theta}-1}{\theta}\right] \qquad \text{where } k<0 \quad (18)$$

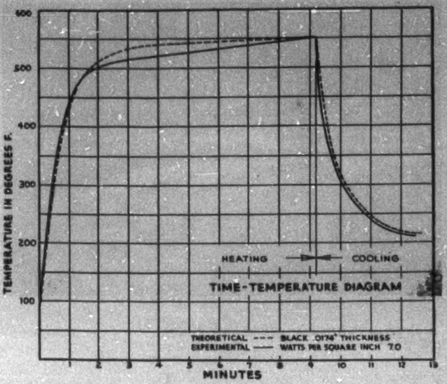

Figure 3. Typical radiant heat time-temperature diagram for a painted steel panel

Using the relation $rw = 17.58\, smh$ (18) becomes

$$\eta = \frac{1}{k}\left[\frac{e^{k\theta}-1}{\theta}\right] \qquad (19)$$

From this equation it is shown that the relation of useful energy retained in the work during the heating cycle to convection and re-radiation losses is a function of time. This is demonstrated graphically for a typical set of operating conditions in figure 4. The work in each case consisted of 24-gauge cold-rolled steel painted with a glossy black finish which reflected ten per cent of the radiant energy received. During this part of the investigation, the oven was allowed to reach an equilibrium air temperature for each of the heat densities employed. The steel was raised from an initial temperature of 80 degrees and the conditions as previously described were such that very little loss might be expected by re-radiation. Whether or not this is the case, no attempt has been made to separate these losses from convected heat as they are valueless. Since figure 4 only accounts for energy that has been absorbed by the work, the complete allocation of energy delivered to the panel surface for a desired working temperature of 300 degrees is shown in table I.

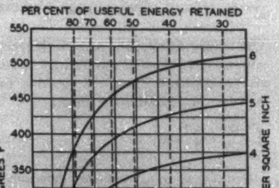

Figure 4. Relation of energy absorbed to useful energy needed for heating a 24-gauge steel panel having an infrared reflection factor of ten per cent

Table I. Relative Energy Distribution at Various Heat Densities for Raising a Typical Black Body to 300 Degrees Fahrenheit

Watts Per Square Inch Received	Allocation of Energy in Per Cent Useful Heat Retained	Reflection Losses	Convection and Re-radiation
3	25	10	65
4	65	10	25
5	76	10	14
6	85	10	5

The per cent of useful energy is not to be construed as an efficiency factor in the sense that it may be compared to efficiencies for other types of ovens since:

1. Energy that may be required to maintain a given working temperature during the heating cycle is not included.

2. The results obtainable at a given temperature may be quite different, particularly for vaporization processes due to a more advantageous rate of heat transfer.

3. Loss before and after the working

Figure 5. Chart for computing time or heat density required to obtain desired temperatures under various conditions of mass and color

If the heat density required to obtain a given temperature in a given time is to be determined, the procedure is as follows: Starting with the given time (for example $1^3/_4$ minutes, at *A*) proceed clockwise following the dashed line successively to the desired temperature (for example 300 degrees, at *B*), to the gauge of sheet steel (for example 20 gauge, at *C*), to color (for example white, at *D*), and finally to *E*, giving the required watts per square inch. If the time required to reach a certain temperature with a known watts per square inch is to be determined, the foregoing process is carried out in reverse fashion, starting at *E* and proceding counterclockwise to *A*

cycle may be virtually eliminated by the instantaneous energy response.

4. Useful energy need not be consumed heating extraneous objects or parts as in the case of nondirectional heating.

5. No account is made of the energy consumed other than that actually reaching the working surface.

6. Convected heat from the working surface and radiant energy sources may also be usefully employed to increase working temperatures.

A comparison of the temperature limits indicated in figures 3 and 4 will demonstrate the importance of the air temperature surrounding the work. The results indicate the relation which frequently exists between uncontrolled experimental conditions and the higher temperatures normally resulting in production practice. The important conclusion to be reached is that within the safe limits of the materials entering an oven, the higher the heat density applied, the quicker will the desired temperature be attained and the greater will be the efficiency of the heat transfer.

The commercial importance of designing ovens for rapid, efficient heat transfer is thus not only shown to be advantageous from a heating standpoint but the consequent time saving affords many practical advantages. Figure 5 graphically demonstrates the time-temperature relations resulting from this investigation for various colors and gauges of sheet steel when subjected to heat densities within commercially available limits. The chart may either be used to calculate needed heat densities for practical installation conditions or to determine the necessary time for obtaining a given temperature at predetermined heat densities.

Production of Energy

Highly efficient sources for producing infrared energy have been available to the electrical industry since Edison's invention of the incandescent lamp, early models of which produced 15 to 20 times as much radiation in the infrared spectrum as in the visible. Although light production has meanwhile been the objective, incandescent lamps today provide many advantages as sources of radiant heat when operated at slightly reduced filament temperatures. With the filament operated in an atmosphere free from oxygen they provide an extremely efficient, long life source having virtually instantaneous response. Very little heat is lost by convection or conduction and the extremely small radiating surface makes for highly efficient control of the useful energy.

Incandescent sources possess the inherent characteristic of producing energy over an extremely broad range of wave lengths, the limits of which are dependent on filament temperature. Since the filament temperature is easily controlled, the effect of various wave lengths on materials which might be subjected to radiant heat is of great interest. Water films, for example, are excellent transmitters of energy at wave lengths below 11,000 angstrom units. Pigments commercially used for paint finishes vary considerably in their absorption characteristics to energy from 7,000 to 30,000 angstrom units. The result is of very little consequence, however, where the pigment is applied on a heat absorbent surface since paint films are customarily of such characteristics that the temperature response is virtually identical, whether the energy is converted from radient to physical form within the film or by conduction from the underlying surface.

Shorter wave lengths approaching the visible spectrum may be reflected, particularly by light colored objects, although the degree of reflection is in no way comparable with that for visible energy. Since energy losses by reflection are of important consequence to the effi-

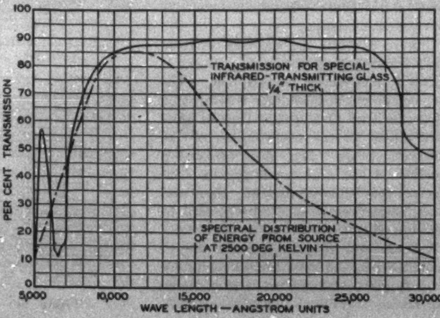

Figure 6. Energy distribution from a radiant heat source and characteristics of an infrared transmitting glass

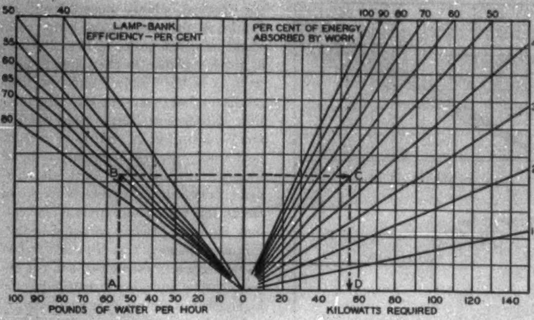

Figure 7. Graphical kilowatt computation for water evaporation

Starting with a given weight of water (for example, 55 pounds per hour, at *A*) proceed clockwise: to lamp-bank efficiency (for example, 65 per cent, at *B*); then to absorption per cent (for example, 50 per cent, at *C*); then to final answer, *D* (in this case, 55 kw). Chart is based on initial water temperature of 70 degrees Fahrenheit

ciency of heat transfer, it is essential that energy subject to reflection be held to a minimum. Conversely the maximum amount of energy must be produced in wave lengths sufficiently short to be efficiently transmitted by the glass enclosing envelope.

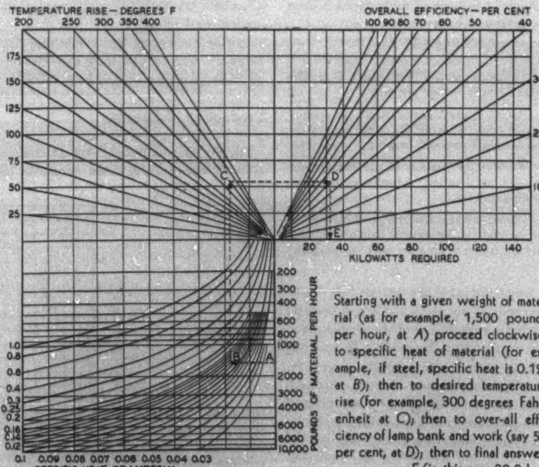
A further consideration is the fact that the surface area of filaments required to radiate equivalent energy is inversely proportional to the fourth power of the absolute temperature. Reductions in operating temperature may then impair the optical efficiency of the system although longer life and reduced glare will result. Qualitative research covering other possible aspects of wave length and energy production are in the formative stages and it is not unlikely that some wave bands may be found more effective for one type of work than another.

Figure 6 shows the spectral distribution of energy from a source operating at 2,500 degrees Kelvin (slightly over 4,000 degrees Fahrenheit) and the transmission characteristics of a special type of glass well suited to the transmission of the infrared energy. This glass converts a portion of the visible energy into convected heat thus minimizing glare and when employed as a lens, may be used to provide advantageous optical control.

Carbon and tungsten sources are in common use. Carbon filaments sublimate more rapidly, however, resulting in faster blackening of the enclosing envelope with consequent reduction in effective life. Tungsten sources are commercially available in larger sizes, facilitating higher heat densities and reducing the amount of associated equipment required for installation. Since filaments operating at 2,500 degrees Kelvin or lower temperatures are materially larger and the rate of sublimation appreciably slower than that for lighting service lamps, the practical life is customarily not directly dependent upon hours of filament service. Lamp blackening in later life may make it essential to replace sources whose usefulness is not otherwise terminated by mechanical failure or electrolysis within the lamp. Such failures are ordinarily not to be construed as being representative of defective equipment as the latter may occur after an appreciable service life when the operating circuit is interrupted. The rapid collapse of the induced field resulting from high current densities in adjacent supply wiring is believed to be responsible. New types of enclosed equipment prevent hazard from such failure. Other problems also encountered in the early periods of development from vibration, high temperatures, and humidity are now quite unlikely with new hard glass sources and proper auxiliary equipment.

Application of Radiant Heat

Radiant heating principles may eventually be employed in many types of heating service. For the present at least, the type of equipment covered by this paper is primarily limited to the low temperature heating of physical objects. The practical temperature limit with present-day equipments is approximately 600 degrees Fahrenheit and the equipment is made to operate at virtually any of the standard industrial distribution voltages. Lamp ratings vary from 250 to 1,000 watts and consequent heat densities may be provided up to approximately ten watts per square inch. Both open and enclosed type reflectors are available with aluminum or gold employed as the essential reflecting surface. Virgin gold provides the highest known reflection of infrared energy. Unfortunately, it has been found to fuse readily with other metals, particularly when subjected to



Starting with a given weight of material (as for example, 1,500 pounds per hour, at *A*) proceed clockwise: to specific heat of material (for example, if steel, specific heat is 0.12, at *B*); then to desired temperature rise (for example, 300 degrees Fahrenheit at *C*); then to over-all efficiency of lamp bank and work (say 50 per cent, at *D*); then to final answer, *E* (in this case 32.8 kw)

Figure 8. Graphical kilowatt computation for heating physical objects

Figure 9. Typical high-heat-density radiant oven—bakes a weather-resistant finish on heavy-gauge parts in 3½ minutes

Figure 10. Typical low-heat-density radiant oven installation

temperatures characteristic in heating service. In this service its initial efficiency of 97 per cent has been found to depreciate to that for the base metal on which it is applied within periods of from one to two years. Aluminum in properly oxidized form, is slightly less efficient initially than gold but particularly when employed in a controlled atmosphere will retain its initial characteristics at fairly high temperature for an almost indefinite period.

The great majority of applications for radiant heating not only require a knowledge of thermodynamics but also of optics, chemical and electrical engineering. Having developed from the field of lighting where the adaptability of the human eye is made to compensate for the many conditions presented, it is, for example, not to be construed that similar flexibility may be enjoyed in the curing of a paint finish intended to withstand weather conditions varying from summer heat to winter cold.

Fortunately for radiant heating, baking processes involving oxidation are very much on the decline. Oils are being replaced by synthetics which will cure by polymerization (combining of double valence atoms to produce an expanded molecular structure) as rapidly as the heat transfer can be effected. Unlike slower oxidizing processes which may continue over an indefinite period if initially incomplete, generally intended results with polymerization require appreciable accuracy both as to time and temperature of bake. Even in the simple case of dehydration processes, competition from generally lower cost fuels compels the careful study of evaporation rate with consequent adjustment in the density of energy applied throughout the operation.

With this type of heating, temperature control, oven adaptability, and the full realization of instantaneous-directional heating advantages, are within the province of the electrical engineer. Numerous types of circuits and interlocked features of operation make it possible to apply heat where and as desired. The ease with which electricity can be controlled as a fuel for industrial heating may well compensate for its higher cost.

Having produced the invisible rays responsible for this type of heating, there is the problem of their proper delivery to the working surfaces to insure consistent and uniform temperatures. This problem is often complicated by the many shapes and sizes of work which an oven may be required to handle. New optical principles have had to be introduced to avoid serious variations in heat density over a practical range of working distances from the equipment and applications involving materials of low thermal conductivity have necessitated improvements in the uniformity of heat distribution.

Most heat sources deliver an appreciable part of their energy in the infrared spectrum although the wave lengths and proportion of convected heat will vary with the temperature of the source. Since the primary difference between radiant heating and other types is in the method of heat delivery, the needed heat capacity of an oven may be determined in the same manner that it would for any other type of heating. For example, if a dehydration operation is to be performed, the liquid must first be raised to a point where its vapor pressure equals or slightly exceeds that of the surrounding atmosphere, and the additional heat of evaporation supplied. In general, water evaporation with radiant heating takes place when the accompanying mass temperature is as low as 160 degrees Fahrenheit, under normal atmospheric pressure. This apparently low temperature, resulting during the withdrawal of the heat of vaporization ordinarily does not exist throughout the entire cycle, thus indicating pressure variations in vapor balance which favor application of radiant heat at the wet end of drying process. Figure 7 shows a graphical means for determining the approximate kilowatt capacity needed for evaporating water at various rates. Similarly the required energy for raising the temperature of a solid may be expressed by:

$$\text{kw} = sM\eta T/3{,}413 \tag{20}$$

where M equals mass per hour, T the time in hours, and η the efficiency. Figure 8 provides a graphical means for determining the required kilowatt capacity of an oven in accord with this formula when the over-all efficiency of heat transfer is known. As previously shown, efficiency varies with the duration of the heating cycle as well as being effected by the many physical factors of oven design. Acknowledgment for the use of charts 7 and 8 is given to the Illuminating Engineering Society and to their author, Howard Haynes.

The several considerations to be made in connection with the proper application of radiant heat emphasize the need for engineering co-ordination. High rates of heat transfer combined with the proper chemistry of materials may in some cases produce phenomenal results. On the other hand, many applications may prove to be entirely impractical while some may or may not be as economical as other methods of heating due to individual conditions.

In principle radiant heating is sound. Its future must rest on its specific merits and the suitability of application which it receives. At the present stage of commercial practice, experimental trials are to be recommended in connection with each application. The resulting oven may employ one or more heat densities for most efficient operation as the controlled rate of heat transfer is the distinguishing feature of radiant energy heating. Figure 9 illustrates a typical high-heat-density installation of 96 kilowatts before draft shields and ventilating equipment have been installed. Figure 10 shows a completed low-heat-density installation of $22^1/_2$ kilowatts.

Advantages and Uses

Numerous advantages may be cited for radiant energy heating in addition to the controlled rate of heat transfer. The high temperature sources provide virtually an instantaneous source of heat, thus eliminating the customary warm-up time for convection ovens. Loss of heat during the warm-up period as well as the consequent loss after each period of operation is also eliminated. Because air temperatures are not raised to comparable convection oven levels, working conditions are frequently more comfortable. The elimination of fumes resulting from combustion fuels also contributes to improved working conditions and in some cases more satisfactory results.

The first cost is invariably low, inasmuch as the structure may be limited to a skeleton frame without insulated walls, doors, or temperature control equipment. Draft shields are ordinarily employed to minimize convection losses and under some circumstances, exhaust hoods may be required above the ovens to remove objectionable fumes. Working temperatures will consistently follow the intended time-temperature response if proper maintenance, voltage regulation, and uniform air conditions are assumed. The semipermanent construction allows the utmost flexibility for plant changes and the proper arrangement of electrical circuits frequently makes for advantageous conversion of the oven to intermittently accommodate varying types or sizes of work. The light-weight construction also permits hanging ovens from the ceiling allowing the free use of floor space below.

Since radiation can be effectively controlled, the energy may be directed or confined to a desired heat pattern or zone of operation. Commercial equipments are available providing various heat patterns so that the utilization efficiency may be of a very high order. This feature also makes possible the design of multiple heat density ovens so that the most effective heat concentration may be applied in each stage of a process and the total cycle consequently reduced to a minimum time. With convection practice this would necessitate sectionalized oven construction, at inherently greater cost.

The direct energy transfer without intermediate heating of steam or air not only facilitates high efficiency but the increased rate with which temperature changes may be effected invariably provides substantial savings in time. Where heating operations are mechanized this simultaneously reflects a corresponding saving in space thus facilitating automatic handling. Many industrial finishes are today being baked in less than two minutes indicating that the proper combination of polymerizing materials and heat application may reduce the time for such baking processes to a small fraction of that characteristic in current practice.

While the source temperatures used in radiant heating are substantially higher than temperatures with combustion or other customary heat sources, the enclosed construction assures relatively low surface temperatures. With a second enclosing envelope employed for optical control and breakage contingencies, the resulting safety from fire or other hazards is of an extremely high order as compared with many other types of ovens.

The effect of humidity in a radiant heat oven becomes practically negligible since the principal mass of air in the oven is at an appreciably lower temperature than that immediately in contact with the work. As a result the air goes through a continuous cycle of heating and cooling; absorbing the vapors when heated in contact with the work and allowing them to condense in colder portions of the oven. This affords a decided advantage for dehydration applications as the convection losses may be materially reduced by a lower rate of air change than would be necessary with convection drying.

At present radiant heat is being employed primarily for the low temperature heating of metals and plastics, the baking of paints and insulating varnishes, and a great variety of dehydration operations. Plans are now in process for extending it into many other fields, particularly where chemical operations may be accelerated. Fuel costs may or may not be directly comparable depending on individual conditions, as one or more of the other operating advantages may produce savings that will very well justify a far more extensive use of electricity in the field of low temperature heating.

Few developments in the last decade have been so revolutionary or have offered such promise for future expansion of the electrical industry as this one which had its inception for production application in the Ford Motor Company. Due credit is accordingly acknowledged to the work of that company and to the many people in the electrical industry who have co-operated in bringing this development forward to a place of respect as a significant tool for industrial use. The author wishes also, to thank his associate F. M. Tiller for his co-operation in the investigation.

Nomenclature

A = area in square inches
d = thickness in inches
h = constant expressing rate of temperature rise without effect of convection
k = constant for convection heat loss in Newton's equation
m = mass in pounds
M = pounds per hour
r = absorption factor
Q = heat in British thermal units per minute
s = specific heat
t = temperature, degrees Fahrenheit
t_0 = temperature of solid before cooling in degrees Fahrenheit

The Application of Ignitrons to Resistance-Welding Control

M. E. BIVENS
ASSOCIATE AIEE

SINCE the development of the ignitron several papers have been presented which pertain to the theory of operation[1,2,5] and explain its contribution to the recent advancement in the field of resistance-welding control.[7,8,9,12] The object of this paper is to review the ignitron characteristics and to point out the operating principles, which should be considered in order to insure successful applications.

In the field of resistance-welding control the ignitron has proved that it possesses a combination of characteristics such as high-current carrying capacity, efficiency, ease of control, reliability, instantaneous operation, no moving parts, quietness, and long life, unequaled by any other device. Therefore a brief description of the design and operation of the ignitron may be desired by those who have not closely followed its development or realized its usefulness as exemplified by its expansion of the field of resistance-welding control.

Construction

Figure 1 is a photograph of a typical water-cooled ignitron, the cross section of which is shown by figure 2. It essentially consists of an evacuated vessel containing a mercury-pool cathode, a graphite anode, and an ignitor for initiating an arc discharge between the cathode and anode at any desired instant during the time that the anode is positive. In this particular design the envelope consists of two concentric cylinders completely closed at the top and bottom and having water inlet and outlet connections, thus serving as the container and the water cooling jacket. A heavy rectangular bar is welded below and perpendicular to the lower header, and thus serves as a means for mounting the tube in an upright position and as the external connection through a large contact area to the mercury-pool cathode within. The top of the tube has a fernico seal supporting a large graphite anode and its external connection is made of heavy copper cable. The ignitor consists of a conically shaped rod of semiconductive material dipping into the mercury pool. It is supported and insulated by a fernico seal extending through the mercury pool and mounted on the header, and through this seal extends the external connection to the ignitor. The tube is exhausted to an extremely low gas pressure and permanently sealed.

Operation

When an electric current of a few amperes and a few microseconds duration is passed through the ignitor into the mercury pool, a cathode spot is formed on the mercury-pool surface. If the anode is positive when the ignitor is energized, a mercury arc is established between the cathode and anode, and persists until the anode current is reduced to zero either by decreasing the anode voltage to a very low value or by means of some external current-interrupting device. The positive-anode voltage may then be re-established and the tube will remain nonconductive until the ignitor is again energized. Since in a-c applications the anode current is naturally reduced to zero at the end of each conducting half-cycle the ignitor control may be regained during the negative half-cycle of anode voltage.

Characteristics

The ignitron can thus be briefly defined as a three-element electron tube having as one electrode a mercury pool provided with a means of instantaneously forming a cathode spot, such that the tube is inherently a controlled mercury-arc rectifier. Since the ignitor provides a means of instantaneously rendering the cathode electron emitting when desired, it avoids the necessity of maintaining a holding electrode during periods of negative-anode voltage and contributes to the ability of the tube to withstand relatively high inverse voltages without the development of cathode spots on the anode which might result in arc-back and reverse current.

The mercury pool has the ability to emit an electronic current of several thousand amperes and to withstand current emission far in excess of the tube average current rating without detrimental effects to the mercury-cathode element which, while being consumed, is replenished by mercury condensation. The current rating is restricted by other considerations. The cathode-anode arc voltage is substantially constant throughout the rated current range and being only about 15 volts contributes to high efficiency, even when the tube is employed in low-voltage circuits.

Application to Resistance Welding

Resistance welding is the process of raising portions of metallic parts to a welding temperature by virtue of the heat developed by an electric current flowing through the resistance of the portions of the metals to constitute the weld. It essentially consists of passing an electric current through metallic parts to be assembled under conditions such that the point of contact between the parts forms the major part of the circuit resistance, thus localizing the heat and producing the desired weld. This usually requires a current of several thousand amperes and

requires clamping the work under considerable pressure between water-cooled electrodes, either stationary or revolving. The magnitude and the duration of the welding current must be independently controllable with a high degree of precision in order to produce welds of the best quality.

When high-quality welds are desired, and in all cases where they are of vital importance, the large welding-current requirement is met by connecting ignitron tubes in the primary of a welding transformer which transforms the energy to a low voltage and higher current as required. Since the ignitron is inherently a controlled mercury-arc rectifier, its application to the control of alternating currents necessitates connecting two ignitrons in inverse-parallel as shown in figures 3, 4, and 5. By means of the ignitor the current through either ignitron may be initiated at the desired instant during the half-cycles that the anode voltage of the ignitron is positive and the reversal of the anode voltage offers the opportunity to interrupt the current at the zero point of the current wave and to regain control during each half-cycle that the anode is negative. Firing the ignitrons at the power factor of the load* furnishes full half-cycles and a sine wave form of load current. Retarding the firing beyond the power-factor angle produces portions of half-cycles of load current and provides a convenient means of controlling the effective value. This is referred to as heat control by the phase-shift method. Thus, two ignitrons connected in inverse-parallel or back-to-back, being instantaneous in operation and capable of carrying several thousand amperes of alternating current, serve as an inertia-less high-speed accurate contactor, actually an electronic contactor with heat control, to meet the exacting requirements of resistance welding. By means of this control transients are eliminated and better welds are made with less line regulation, less heating in the welding transformer, and with longer electrode life.

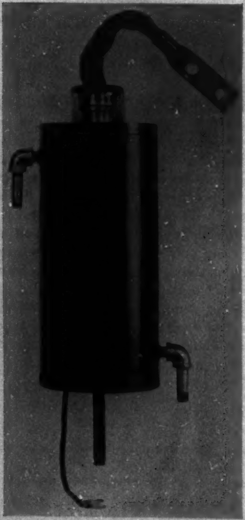

Figure 1. Type FG-258A water-cooled ignitron

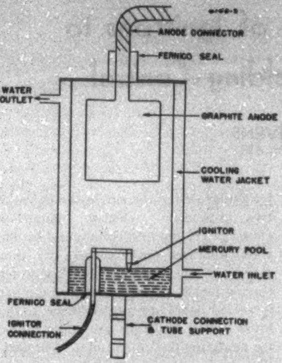

Figure 2. Schematic cross section of ignitron shown in figure 1

The ability of ignitrons to pass large currents with instantaneous response, in conjunction with the development of thyratron precision timing controls, has made large welding currents as short as one cycle practical and short accurate timing periods have greatly improved the technique of resistance welding, speeded up production methods, and extended the field of resistance welding to highly conductive nonferrous metals having critical welding temperature ranges.

The application of thyratron precision timing controls and ignitrons to resistance welding includes entirely too large a variety of circuits to be more than mentioned here. They include applications of spot, pulsation, and seam welding controls, to spot welding, projection welding, butt welding, flash welding, and seam welding, which have been adequately covered by preceding papers.[9,10,11]

Precision Ignitron Control

Thyratrons are more suitable than ignitrons as measuring devices and therefore in cases where precision timing and firing are required, they are used for the more delicate operating functions and in response to low energy voltage controls furnish ample ignitor current to insure firing the ignitrons in a manner similar to the use of a sensitive relay for controlling a large contactor or oil-circuit breaker. The circuits shown in figures 4 and 5 embody most of the operating principles which must be considered in the applications of ignitrons. Figure 4 for precision control of welding current will first be considered. The time of conduction of the ignitrons is controlled by the firing thyratrons in the ignitor circuits. The firing thyratrons are controlled by associated precision timing circuits which determine the duration of the weld, the time between welds, the number of welds, etc. This circuit provides a convenient method of heat control by the phase-shift method. Considering a half-cycle when line $L2$ of the power supply is positive, the full-line voltage is applied as the anode voltage for the firing thyratron 1 and the ignitron A until the firing thyratron 1 is rendered conductive by the associated control. At the instant of firing, the ignitor current is chiefly determined by the instantaneous value of line voltage, the ignitor resistance, the value of the current-limiting anode resistor $R1$, and the welding transformer load. An arc is initiated in the ignitron applying substantially full-line voltage to the load and reducing the firing thyratron anode voltage to such a low value that the ignitor current is extinguished. The load current then continues in a natural manner until it attempts to pass through zero, its continuance then being similarly dependent upon the conductivity of firing tube 2 and ignitron B. If the firing point is adjusted to occur at the power factor of the load the first half-cycle of current will always be of normal wave form (steady-state value) for the full heat condition. This corresponds to the wave form of current shown by the solid trace in figure 6. Preventing firing in advance

---

*In this paper references to the power factor of the load mean the power-factor angle where the welding-transformer primary current passes through zero during steady-state conditions with the secondary closed on the work to be welded. This power-factor angle is intermediate to the corresponding power-factor angles of the exciting current and load-current components of the primary current. The accepted practice is to initially energize the welding transformer at the natural zero point of the primary current wave (except where phase control is used) which results in negligible transient in the primary current.

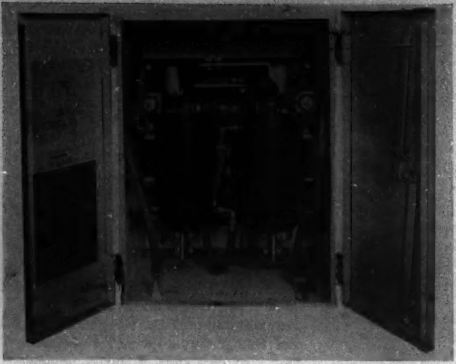

Figure 3. Ignitron contactor

of this point avoids the possibility of beginning the weld with a transient starting current with the first cycle having a magnitude and time duration exceeding that of the normal sustained value. If the controlled firing occurs later than the natural power factor of the load, the wave form of current and welder voltage will be as shown by the dotted current trace and cross-hatched portion of voltage shown in figure 6, resulting in a reduced heat condition. In any case the welding current is interrupted near the natural zero point of the current wave.

The operating principles which must be considered in order to insure successful operation of ignitrons can most easily be explained by referring to the wave forms of currents and voltages in the component circuits. An understanding of the wave forms existing during normal operation will assist in checking correct application and in detecting cases of abnormal operation which may be caused either by misapplication or defective tubes. Observing the form of circuit voltages by means of a cathode-ray oscillograph is the most satisfactory method of checking the operation. Due to the strong-stray magnetic field near a welding transformer and welder during operation, and due to the high sensitivity of the cathode-ray oscillograph, it is usually necessary to place the oscillograph somewhat distant from the welder and in the position for minimum response to the magnetic field.

The wave forms for different voltages and currents are drawn separately in figures 7*a*, 7*b*, and 7*c*, which show the conditions corresponding to full heat, medium heat, and minimum heat, respectively. These wave forms are shown for a lagging power-factor load which is usually between 60 degrees and 85 degrees for a welding transformer and in which case a full half-cycle of current can be conveniently initiated by virtue of the fact that considerable line voltage is available at the desired instant of firing.

Furthermore, the firing tube operates into a more resistive load than the ignitron welder load and the full heat firing point corresponds to a retarded firing angle for the thyratron. This facilitates obtaining a steep wave front of ignitor current which assists in quickly starting the ignitron. However the minimum heat adjustment for reliable starting is limited because of the low voltage near the end of the half-cycle. The minimum instantaneous ignitor voltage required for reliable starting is considered as being about 200 volts. To this must be added the normal 15-volt drop in the firing thyratron and the voltage drop across the anode current-limiting resistor. The recommended value of anode current-limiting resistance is four ohms for 440- or 550-volt supplies, and one ohm for a 220-volt supply. The instantaneous starting current required for reliable operation of a normal ignitron averages about 20 amperes, but it is recommended that a minimum of about 40 amperes be furnished. The minimum heat adjustment should therefore be restricted from firing beyond the 143-degree point of a 440-volt supply voltage or the 128-degree point of a 220-volt supply voltage.

Considering the limitation imposed by a 220-volt supply, with an 85-degree (0.087) power-factor load, the 128-degree point on the voltage wave corresponds to 43 degrees angular delay in firing. This reduces the effective current to about 28 per cent of the full value or the heat to about 8 per cent of full heat. A 60-degree (0.5) power-factor load permits an angular delay of 68 degrees and reduces the current to about 24 per cent or the heat to about 5.8 per cent. Firing at the 143-degree point of the voltage wave as permitted by a 440-volt supply reduces the current to about 13 per cent (about 1.7 per cent heat) in the case of an 85-degree power-factor load, and reduces the current to about 11 per cent (about 1.2 per cent heat) in the case of a 60-degree power-factor load.

It should be observed that firing at the 128-degree point on the voltage wave (or firing at the 143-degree point on the voltage wave) causes a little greater reduction in heat in the case of a 60-degree power-factor load than in the case of an 85-degree power-factor load. The phase-shift circuit used for heat control is such that the full heat adjustment prevents retarding the firing angle as far on a high power-factor load as it permits when adjusted for a low power-factor load. Consequently, if the full heat adjustment is correctly made the minimum current setting will be substantially independent of the power factor of the load considering the usual range of power factors of resistance welders. Therefore, control panels of the most recent design have heat control dials precalibrated from 20 per cent to 100 per cent current which provides a range from 4 per cent to 100 per cent heat. However, when operating from a 220-volt supply, current settings less than

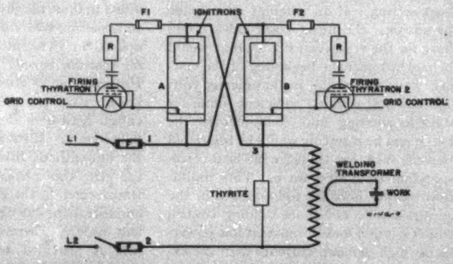

Figure 4. Schematic diagram showing precision control of ignitrons

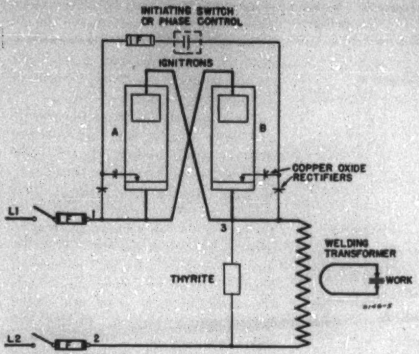

Figure 5. Schematic diagram of Ignitron contactor

40 per cent (16 per cent heat) are not recommended.

When operating at reduced current there are always zero-current gaps in the current wave as shown by the upper traces in figures 7*b* and 7*c* but the wave form of the individual current impulses or portions of half-cycles is appreciably affected by the nature of the load, that is whether the load is resistive, inductive, or capacitive, and also whether the combinations of resistance, inductance, and capacitance are effectively in parallel or in series. The series characteristic nearly always prevails in resistance-welding control circuits. In the case of the low heat condition—figure 7*c*—the effect of the inductive portion of the load is distinctly noticeable. As the load is made more resistive the current wave form naturally more nearly approaches the wave form of the voltage applied to the load or welding transformer. If the firing point for a pure resistance load were the same as shown in figure 7*a* for full heat for a given inductive load, the load voltage wave form would consist of only the first and third segments of voltage shown for the case illustrated. The current wave forms would be substantially similar and this would obviously correspond to a reduced heat setting. If an attempt were made to advance the firing point toward full heat for the resistive load, a point would be reached near the beginning of the voltage wave where the instantaneous voltage has not attained sufficient value for reliable starting and consequently the maximum heat setting would be restricted to some value less than the full heat corresponding to a sine wave. This limitation usually is of no consequence in the application to resistance-welding control which is noted for intermittent low power-factor high-demand currents with the exception of small bench welders which having high power factors and requiring comparatively small currents may require supplementary shunt loading.

A low power-factor load is of course objectionable from the power-supply viewpoint and therefore power-factor correction to unity power factor or even a leading power factor is sometimes applied. Therefore, in such cases the series capacitor method of power-factor correction is employed.[13] This introduces the difficulty of firing the ignitrons for full heat on unity power-factor load at which instant there is no line voltage available for firing. The difficulty is readily overcome by precharging the capacitor which thus provides a voltage for firing at the zero point of the line voltage wave. Controls may be used which insure that an even number of half-cycles of current are supplied to the load and since the current is naturally interrupted at the zero point on the wave the series capacitor is left charged with the correct polarity for initiating the next weld.

Under normal conditions the firing thyratron is only required to furnish an ignitor current of very short duration once each cycle at the instant that ignition is desired. An anode resistor is provided to limit the thyratron anode current to a permissible value for instantaneous operation. The medium time required for ignition is only a few microseconds. However, due consideration must be given to the possibility that a short-circuited ignitor or defective ignitron may fail to start. If the ignitron fails to start, the hot-cathode thyratron is required to energize the primary of the welding transformer to the extent limited by the anode resistor during the remainder of the half-cycle. Therefore a three-ampere fuse is provided to protect the firing thyratron and serve notice in event that the demand on the thyratron is excessive. Normally the ignitor current has a sliver-like wave shape as shown by the lower solid traces in figures 7*a*, 7*b*, and 7*c*. Its wave form can be readily determined by observing the wave shape of the voltage drop across the firing tube anode resistor. If the ignitron is hard starting it will be revealed by a voltage trace showing that the firing tube conducts current for a time longer than for normal instantaneous ignition, as shown by the dotted traces in figure 7*a*. In the extreme case where the ignitor is energized but the ignitron fails to fire at all, either the anode fuse will blow or the trace of firing tube anode current will approach the wave form of the line voltage during the period of conduction. In such cases it should be determined whether the ignition failure is due to a defective ignitron (for example, an ignitron contaminated by foreign gas or having a wet ignitor) or due to misapplication such as attempting to operate a load drawing insufficient current for ignition or attempting to fire the ignitor with insufficient voltage such as might occur at full heat on a resistive load or at minimum heat on a reactive load. Tests should not be made while the secondary of the welding transformer is open-circuited because the exciting current may not be sufficient to provide reliable starting of the ignitrons and may exceed the rating of the firing tubes. After ignition the load current must also be sufficient to maintain the cathode-to-anode discharge in the ignitron after the ignitron is started. The subject of supplementary loading to improve the ignitron operation for lightly loaded welders will be dealt with later.

On the other hand the absence of any trace at all of voltage across the firing tube anode resistor would show that no ignitor current flows but this should be most readily noted by observing that the firing tube does not glow. Such an occurrence might be due to the ignitron being tilted so that the ignitor fails to contact the mercury pool or due to the firing tube anode fuse being open.

It is always desirable, and sometimes necessary, to prevent initiating the welding current in advance of the power-factor angle of the welding transformer in order to avoid transient currents. The power factor is usually about 70 degrees. Therefore, ignitron controls provided with synchronous precision timers but without heat control are adjusted at the factory to initiate the welding current at 70 degrees power factor. Ignitron controls provided with heat control (phase control) are adjusted to prevent advancing the full heat setting ahead of 70 degrees power-factor angle. The effect of a transient starting current produced by firing ahead of the power-factor angle depends upon whether it is applied to spot welding or seam welding and upon whether or not it is associated with phase control, the results being quite different. In the case of spot welding without phase control, since the transient accompanying synchronous starting is consistent and since the welder secondary circuit is opened after each weld, the transient in some cases may be tolerated. When phase control using peaked firing signals is provided, firing in advance of the power-factor angle cannot be tolerated for the following reasons: The first half-cycle of transient starting current will have a duration greater than 180 degrees, and will prevent initiating the next half-cycle of opposite polarity at the 180-degree point when the next firing peak occurs. Therefore, when the first half-cycle of current decreases to zero the peaked firing signal for the second half-cycle has already occurred and there is no ignitor excitation for the corresponding ignitron with the result that only positive half-cycles of current are furnished to the welding transformer and furthermore the starting transients may be accumulative. It is recommended that all installations be checked, and readjusted if necessary, to insure that there is no possibility of initiating the welding current in advance of the power-factor angle. This can most satisfactorily be accomplished by observing the wave form of the voltage across either the ignitrons or the primary of the welding transformer by means of a cathode-ray oscillograph and in consideration of the following.

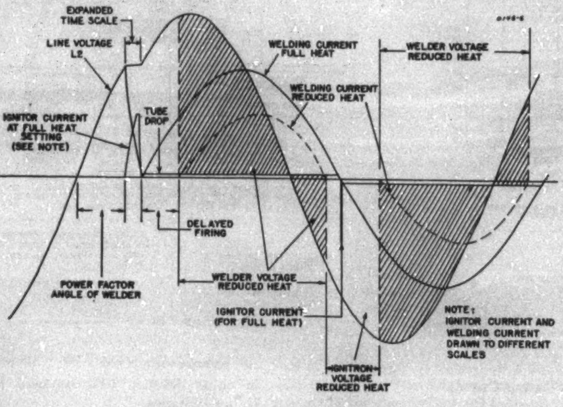

Figure 6. Current and voltage wave forms under phase-controlled conditions

If heat control is not provided it is merely necessary to observe whether or not the first few cycles of welding current are balanced. This can most conveniently be done by using a short-timing axis. In the case of heat control the wave forms should be observed. For example, considering the transformer primary voltage wave form as illustrated in figures 7*a*, 7*b*, and 7*c* when the heat control is advanced toward full heat the gap representing zero-primary voltage should decrease but not disappear until the full heat setting is reached. Conversely, as the heat control is advanced the line voltage across the ignitrons should not disappear until the full heat setting is reached. It will likely be observed that satisfactory operation can be still obtained if the phase control is advanced to the extent that the cathode ray barely shows a trace of line voltage during current transfer in the ignitrons, but it is recommended that the full heat setting be limited to allow a narrow trace of line voltage across the ignitrons during the current transfer (or a small gap for zero voltage across the primary of the welding transformer) to take care of variations in power factor of the welding transformer secondary circuit due to change of the welder throat dimensions, changes in amount of magnetic material in the throat, etc.

A few amperes of current are required to maintain cathode-to-anode conduction in an ignitron. When the anode current decreases below a few amperes the vapor-arc discharge may suddenly become extinguished. Therefore a resistance or thyrite unit is always connected across the primary of the welding transformer to suppress the generation of high voltage due to the sudden interruption of current.

The large supply current required by resistance welders usually causes considerable voltage regulation at the welder. The cathodes of the firing thyratrons have an appreciable thermal capacity for maintaining emission during reductions in cathode supply voltage of short duration, but long spot welds or seam welding accompanied by considerable voltage regulation may tend to shorten the life of the firing thyratrons on account of reduced filament voltage, and should be avoided by obtaining the control voltage from a location nearer the source.

Supplementary Loading

It is considered that the minimum current that can satisfactorily be controlled by ignitron tubes is 40 amperes. For currents less than 40 amperes, a shunt resistor or reactor must be connected across the primary of the welding transformer. The amount of the additional loading required depends to some extent on whether the shunt load is mostly resistive or reactive. That is, if the resultant load is made more resistive the full heat firing point for the welder will correspond to a retarded firing angle for the shunt-resistive load and the ignitor starting current can build up more rapidly than in the case where the shunt load is reactive. Therefore, a resistive load is preferable and a 25-ampere resistor load is considered adequate.

Ignitron Contactor

In some resistance-welding control applications it may be felt that the cost of thyratron synchronous precision timing control is not warranted but the use of ignitron contactors with their high speed, quiet operation, and low maintenance is desirable. The ignitron-contactor circuit shown in figure 5 is being used for such applications with the timing provided by some auxiliary device, such as a cam or vacuum-tube timer.

One convenient method of energizing the ignitrons is to connect them in series back-to-back across the ignitron cathode-anode circuits which are connected in inverse-parallel. A fuse is located in the

series ignitor circuit which also includes the initiating switch. This would necessitate one ignitor carrying reverse current during the instant that the other ignitor passes forward current for the ignitron having a positive voltage during the half-cycle considered. It is necessary to avoid passing reverse currents through ignitors and therefore copper-oxide rectifiers are provided to by-pass the reverse current. A low value of resistance usually four ohms directly in series with each ignitor contributes to the shunting effect of the copper-oxide rectifier for reverse currents. Using another rectifier instead of the resistor in series with the ignitor so that the rectifier readily passes forward ignitor current but tends to block reverse current reduces the ignitor current substantially to zero and improves ignitor life. If phase control is desired, the phase-control unit can be conveniently connected directly in series with the external initiating switch. The ignitron contactor with phase control prevents high-transient starting currents.

Rating Curves

Ignitron tubes are designed in various sizes having current ratings closely following a preferred number series. As previously stated their continuous-current rating is chiefly limited by the maximum allowable mercury-vapor pressure caused by arc heating—the permissible electron emission of the cathode being far in excess of this value. However, the greatest benefits of ignitron characteristics are obtained in their application to intermittent, short-time, high-current demands as required for resistance welding. In rating the ignitron the average current, effective current, and peak currents must be considered and the main criteria are to limit the current density accompanied by a high instantaneous mercury-vapor pressure and to limit the degree of ionization at the instant the anode voltage becomes negative. These limitations must be recognized or conditions leading to "shoot through"* and "arc back"** may occur, thus permitting current conduction in either direction unaccompanied by ignitor excitation.

In comparison, the intermittent current rating of a cable or a welding transformer can be determined from its continuous-current rating and the duty cycle, with consideration of its ability to radiate heat during short-time intervals. (In these applications where the load is intermittent, cable size is usually determined by its effect on voltage regulation, instead of the heating.) For example, if a conductor is capable of carrying a given current continuously, it is capable of carrying an intermittent current $I_t = I_c/\sqrt{D}$ where D is the duty cycle or percentage of time that the current flows. Since the ignitron operates at a substantially constant voltage drop, the heat loss is more nearly proportional to the current instead of the current squared. Intermittent current ratings tend to follow this characteristic except that other factors must be considered. In order to specify the

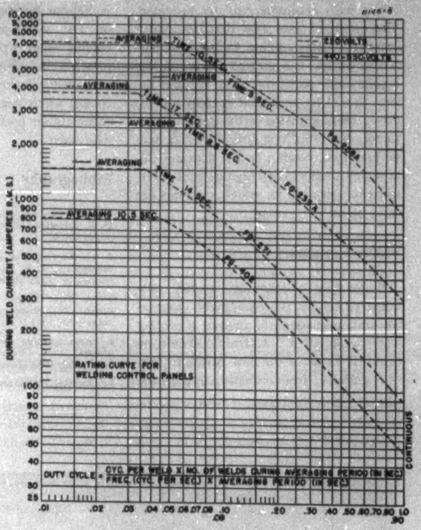

Figure 8 (above). Rating curves for resistance-welding control panels

current rating of an ignitron it is necessary to provide rating curves as shown in figure 8 which have been established after due consideration of the many determining factors involved. These curves give the permissible effective demand current (rms current during the weld) for different duty cycles or percentage of the time that the ignitrons are conducting. The rating curves are given for resistance-welding control panels in which case two ignitrons are connected in inverse-parallel. The duty cycle can be conveniently calculated by means of the formula given. Referring to the curve for the FG-258A ignitrons it will be observed that they will conduct 900 amperes continuously or 5,300 amperes at nine per cent duty cycle when operating from either 220-, 440-, or 550-volt power supplies. It is considered advisable to limit the current to this value when operating at lower duty cycles from 440 or 550-volt power supplies, but when operating from a 220-volt supply a current of 7,000 amperes is permissible if the duty cycle is less than five per cent, as is frequently the case in high kilovolt-ampere spot welding. Of course, this is the current which may be directly controlled through the primary of the welding transformer, the secondary current may be several times this value (depending upon the turns ratio), and in some cases is as high as 100,000 amperes or more. When determining the duty cycle there is a maximum allowable averaging time which depends upon the supply voltage and type of tubes as specified on the rating sheet. This averaging time limits the duration of the weld or the spot length at any current to a value which will not produce excessive internal tube temperature at the end of the spot.

The maximum permissible spot length at a given value of current can be readily determined from the tube-rating curve by multiplying the corresponding duty cycle by the averaging time of the tube. For example, considering the FG-258A ignitrons a 220-volt power supply and 5,000-amperes demand current, the maximum permissible spot length is 0.1 by ten or one second, in which case the interval between welds must not be less than nine seconds. That is, the duty cycle corresponding to a given value of current times the rated averaging time of the tube in cycles is equal to the maximum permissible number of conducting cycles during the averaging time. This applies to spot welding, pulsation welding, or seam welding. Considering a case of seam welding at 60-per cent duty cycle (for example, three cycles on, two cycles off, three cycles on, etc.), the type FG-258A ignitrons will allow a demand current of 1,500 amperes at either 220, 440, or 550 volts. The maximum permissible "on period" or the maximum spot length at 1,500 amperes is limited to six seconds during a ten-second interval when operating from a 220-volt supply, or three seconds during a five-second interval when operating from a 440- or 550-volt supply.

As previously explained, copper-oxide rectifiers are used in the ignitor circuits of ignitron contactors for the purpose of preventing reverse ignitor currents. The copper-oxide rectifiers can be designed with sufficient elements in series-parallel that they will allow the full rating of the ignitrons to be utilized. However, economic considerations necessitate a study of the unusual operating condition to which the rectifiers are subjected, in order to insure that rectifiers having adequate rating with minimum cost are provided. The results of tests show that low-ignitor currents, corresponding to low-load currents, impose the greatest duty on the copper-oxide rectifiers. The rectifier design should be such that it does not increase this limitation of the ignitron contactor, except at long duty cycles as may be justified. Such a design does not impose any limitation to high-current intermittent operation for which ignitrons are most useful.

Water Protection

Water-flow switches are usually provided to render the equipment inoperative unless an adequate amount of cooling water is provided. A strainer should be installed ahead of the flow switch to prevent sediment from collecting in the tube jackets or interfering with the operation of the water-protective device. The cooling water is passed through the tubes in series and should enter the bottom of each water jacket in order to keep the coolest water near the mercury pool and eliminate air pockets which might otherwise occur.

Fault Voltage Drop and Impedance at Short-Circuit Currents in Low-Voltage Circuits

O. R. SCHURIG
MEMBER AIEE

Synopsis: In the paper are presented new data on (1) arc-voltage drop and current-limiting effects for arc faults in bar-conductor structures, (2) current-limiting effect of insulated-cable arc faults, (3) cable impedance in an iron conduit, and (4) impedance of low-voltage switchgear circuit assemblies, derived from tests at short-circuit currents in circuits with open-circuit line-to-line voltages of 208–600 volts at 60 cycles. The currents ranged from less than 10,000 amperes to values as high as 100,000 amperes rms in some cases.

The new data dispel several illusions with respect to accidental faults in low-voltage bus structures and other low-voltage gear. Contrary to inferences frequently drawn from previously published data, the paper shows that

(*a*). Faults in the typical low-voltage bus structures tested are not self-clearing.

(*b*). Fault arcs do not show the drastic current-limiting effect which they are frequently assumed to exert upon short-circuit currents. Instances are shown where actual fault currents reach 100 per cent of the rms symmetrical values calculated for *bolted* faults.

This study shows a self-clearing tendency for representative types of accidental faults in cable, but it was found that a large current-limiting action prior to current interruption cannot be depended on.

The new data, supplementing existing impedance data, definitely indicate the possibility of reasonably accurate calculation of short-circuit currents in low-voltage circuits. The magnitude of fault currents actually obtained shows the fallacy of applying arbitrary and large discount factors to calculated short-circuit current values or of establishing arbitrary "maximum" values of current obtainable in low-voltage circuits and systems.

Introduction

THE impedance determining the magnitude of short-circuit currents in low-voltage distribution circuits (600 volts and below) includes (1) that of power sources, lines, and step-down transformers, and (2) that of conductors, circuit breakers, control equipment, and other devices in the distribution circuit up to the point of short circuit. While it has been well known that the impedances of the various connections and devices in the distribution circuit often have an appreciable reducing effect upon the short-circuit current, different calculating procedures have been used to take into account their effect upon the magnitude of short-circuit currents. One of the least known factors affecting the magnitude of short-circuit currents for various kinds of arc faults has been their voltage drop and current-limiting action.

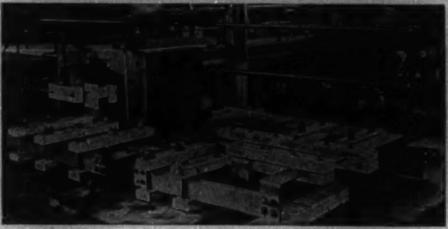

Figure 1. Metal-enclosed bus assembly with connections for tests of fault voltage across short-circuit arcs

Shows upper bus and lower bus at right angles to each other. Connections to lower bus removed. Tests were made with opening at power-supply end of enclosure, as shown

A method often used is that of applying a fixed reduction factor to the current calculated on the basis of the impedance from the power source up to and including the step-down transformer. Stieber[1] gives an approximate rule whereby the combined drop due to arc voltage at an arc fault and lead resistance is taken as approximately 50 per cent of the line voltage in 440-volt circuits and advocates allowing for these drops by a 50 per cent reduction of the current calculated on the basis indicated above.

Another arbitrary short-cut method is that of using a fixed maximum value of short-circuit current for all kinds and sizes of circuits. Fixed values ranging from 20,000 to 40,000 amperes have been suggested as representative estimates of the maximum probable short-circuit current in circuits of 600 volts and less. Stieber[1] concludes that "most of the larger 440-volt installations can be readily handled by breakers having momentary ratings and interrupting capacity of 20,000 amperes; in a few special cases 40,000-ampere ratings are required."

Proponents of the 50 per cent reduction factor and of the fixed values of maximum short-circuit current have cited the following tests by Papst[2]: In a circuit fed from a 20,000-kva generator through a low-resistance, 3,000-kva step-down transformer, in which the calculated short-circuit current at the low-voltage terminals of the transformer was 200,000 amperes, a maximum short-circuit current of 68,500 amperes was obtained in a bus remote from other conductors when the short circuit was initiated by a copper bar, hinged to one of the busses, falling upon the other bus bar. The copper bar was quickly repelled and interrupted the circuit in the first half cycle.

Other tests[3] using the same power source gave a maximum peak current of 24,000 amperes when a screwdriver was dropped across the same bus bars. Furthermore, a current of 17,000 amperes crest was obtained when a copper wire 0.075 inch diameter, was dropped across the busses. In both of these cases also the short circuit was interrupted at the fault within the first half cycle.

However, for short circuits close to the step-down transformer, the impedance of the metallic connections and devices from the transformer to the point of short circuit is ordinarily far too small to account for anything like a 50 per cent reduction of current, or a maximum value

---

Paper 40-148, recommended by the AIEE committee on industrial power applications, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted August 13, 1940; made available for preprinting September 9, 1940.

O. R. SCHURIG is a member of the general engineering laboratory staff of the General Electric Company, Schenectady, N. Y.

Acknowledgments are gratefully made to Mr. A. G. Darling for his contributions during the various stages of the investigation, to C. H. Black and A. B. Anderson for their co-operation in the promotion of the testing program, and to Mr. J. H. McAllister for his assistance in the calculation of the test results. Appreciation is also expressed to the staff of the switchgear testing station of the General Electric Company at Schenectady for their co-operation in the various tests.

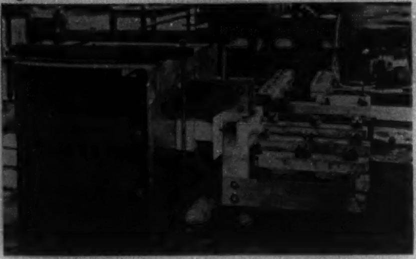

Figure 2. Rear end of metal-enclosed bus assembly for measurements of fault voltage across short-circuit arcs

Rear wall of sheet metal enclosure, normally closed, was removed after tests to show interior of bus assembly. Upper bars were sprung from their end supports by the action of short-circuit forces. Ends of upper bars badly burned in the course of arcing tests

of current limited to, say, 20,000 or even 40,000 amperes in the case of larger 440- or 550-volt installations. The short-cut methods mentioned, therefore, cannot generally be relied on to give correct predictions of short-circuit current for bolted short circuits or for faults nearly equivalent thereto when the short circuit is close to the power-supply mains. Trencham and Mortlock[3] concluded from an analysis of distribution-circuit impedances, that a fixed reduction factor applied to currents calculated from generator and transformer reactances alone cannot be used generally because of the large variations in conductor impedances and other impedance values to be considered.

Furthermore, the large current-limiting effects—obtained when objects, which are readily repelled, are dropped across bare conductors without an enclosure and remote from other live bar conductors—could not be expected in typical low-voltage structures where the presence of connection bars and the use of relatively small spacings result in congested assemblies similar to those described below. Slepian and Strom[4] found that short arcs between bare copper bars one-fourth-inch apart have arc voltages ranging from only 40 to 100 volts, at currents from 2,500 to 6,400 rms amperes.

Arc-fault characteristics of low-voltage cables have been investigated by Kehoe,[9] by Sutherland and MacCorkle,[10] by Slepian and Strom,[4] and by others, with particular reference to burn-off and reignition characteristics. Little conclusive information has been available, however, on the current-limiting effect of cable-fault arcs in circuits with available short-circuit currents in excess of 20,000 amperes.

In order to provide data on arc-voltage drop and current-limiting effect of arc faults in typical low-voltage structures and in cables, as well as more complete data on impedance of conductors and devices up to the point of fault, a series of fault-arc tests and impedance tests at short-circuit currents was made including the following items:

Fault-voltage drop for arc faults of various kinds

(*a*). **Between bare conductors in a metal enclosure, using both double-bus and single-bus assemblies.**

(*b*). **In three-conductor 350,000-circular-mil cables, not enclosed.**

Impedance of a three-conductor 350,000-circular-mil cable in an iron conduit.

Impedance of low-voltage switchgear circuit assemblies, of protective and control equipment.

In these tests the open-circuit line-to-line voltage ranged from 208 to 600 rms volts, at 60 cycles.

It is the purpose of this paper to present the more significant results of these investigations.

I. Fault Voltages and Current-Limiting Effect for Short-Circuit Arcs in Bar-Conductor Structure in Metal Enclosure

The metal-enclosed bus-bar assembly of figures 1 and 2 was used having bare copper bars four inches by one-fourth inch in a three-phase circuit with face-to-face bars spaced two inches on centers. One series of tests was run with two sets of bars, one set $1^3/_4$ inches above and at right angles to the other set of bars, as shown in figure 3. Both sets of three-phase bars were connected to the power-supply conductors through rigidly supported bars, so that both sets of bars would be simultaneously and continuously energized with voltage for the duration of each test, as shown in figure 4.

The purpose of the tests was to obtain information on arc-voltage and current-limiting effect of faults that would roughly correspond to nonbolted faults in typical low-voltage bar-conductor structures. Light wires, 0.045-inch diameter bare copper, and bare 250,000-circular-mil stranded cable, loosely placed across the bars, were used to initiate the faults, as shown in figure 3. The impedance of the metallic circuit was largely reactive, comprising a generator, adjustable reactors, bare copper connections and transformers. Open-circuit line-to-line voltages ranging from 300 to 600 volts rms were applied to the test assembly. Further details pertaining to test conditions are given in the appendix.

The following results were found, as indicated by the tabulated summaries, tables I and II, and by the curves of

Figure 3. Arrangement of bars and of means for initiating arc faults at short-circuit currents in metal enclosure

Bars 4 inches by 1/4 inch spaced 2 inches on centers. Enclosure (not shown) 36 inches long, 24 inches high, 20 inches wide. Supporting members and braces of molded material, not shown. Connections to test bars not shown. Shaded areas indicate parts of bars within enclosure. Short circuits initiated (*a*) by doubled bare copper wire 0.045 inch diameter about 4 inches long, (*b*) by bare 250,000-circular-mil copper cable about 2 feet long

***250,000-circular-mil copper stranded cable laid across upper bars. Test box included one set of bars (upper) only.

figures 6, 7, and 8 (for an outline of the procedure used in evaluating the results, see the appendix):

(*A*). Of particular interest are the minimum values of arc voltage, as follows:

(1). For faults initiated in the lower bus in the double-bus assembly, the minimum arc voltage was in the vicinity of 100 volts crest, line-to-neutral value, average per phase, for three-phase faults, at 1$^{3}/_{4}$ inches minimum conductor clearance, for a line-current range from 10,000 to over 120,000 amperes crest.

At 300 volts open-circuit voltage, one or two arc-voltage values below 100 volts crest were obtained; while at 600 volts open-circuit voltage the lowest value was about 10–20 per cent in excess of 100 volts crest. However, sufficient tests were not made for each voltage to indicate conclusively whether there is a material difference between the minimum arc voltage in 600-volt circuits and that in 300-volt circuits.

It made no material difference in the magnitude of the minimum arc voltage, or in the range of arc voltage, whether the arc was initiated by the small wire or by the 250,000-circular-mil cable.

(2). For faults in the single-bus assembly, the minimum arc voltage was of the order of 160 volts crest, line-to-neutral value, for currents up to 40,000 amperes crest at 300 volts open-circuit voltage, and was 220 volts crest or higher, line-to-neutral value, at 600 volts open-circuit voltage, at currents from 50,000 to 120,000 amperes crest.

(*B*). The faults were not self-clearing, but endured till the station breaker interrupted the circuit elsewhere after six to ten cycles.

(*C*). The current-limiting action in the enclosed-bus arc tests in question is summarized in table II, showing in the double-bus assembly, values from 72 to 100 per cent of the available short-circuit current (the latter determined for bolted short circuit); and in the single-bus assembly, values from 57 to 90 per cent of the available current.

(*D*). Although the faults started as single-phase line-to-line faults, they usually developed into three-phase short circuits within less than a half cycle and continued as such.

PROCEDURE FOR ESTIMATING SHORT-CIRCUIT CURRENTS IN CIRCUITS WITH ARC FAULTS

The arc voltages for different kinds of faults in low-voltage circuits will vary depending on

The conductor spacing between phases,
The spacing between adjacent circuits,
The type of construction, whether open or enclosed,
The clearances to ground and to enclosing walls,
The type of conductors, whether bare or insulated,
The manner in which the fault is initiated,
The character of the enclosing walls, etc.

It will not be attempted to consider all of these in detail. Some of the fault conditions of particular interest in low-voltage switchgear construction are those caused by conductors dropping across phases in the following types of structures:

(*a*). Heavy-current bar-conductor assemblies with low to minimum spacings, metal enclosed, with two or more bar-conductor circuits in close proximity to each other.

(*b*). Bar-conductor circuits, remote from other live conductors, metal enclosed.

Less severe types of faults than those for (*a*) and (*b*) above may occur in open bar-conductor circuits remote from live conductors, and may give rise to short-circuit currents with more pronounced current-limiting effects.

When low to minimum clearances are used in structures of types (*a*) and (*b*) above, short-circuit currents due to objects (which are capable of being repelled or destroyed) bridging across phases may be roughly estimated by the following procedure, with the aid of the arc-voltage data given here in figures 7 and 8.

Basis of formulas:

As a first approximation, the voltage equation 1 for three-phase short-circuit including arc may be written assuming sine-wave voltages and currents:

$$E-v-ri-jix=0 \quad \text{rms volts to neutral} \quad (1)$$

Symbols:

E = 0.58 × (line-to-line voltage of circuit)
v = 0.71 × (crest value of arc voltage to neutral from figure 7 or 8, as required)
i = rms symmetrical short-circuit current, amperes
$j=\sqrt{-1}$
r = resistance of metallic circuit, ohms per phase, as determined for bolted fault
x = reactance of metallic circuit, ohms per phase, to the point of fault

Table III. Comparison of Calculated and Measured Values of Short-Circuit Currents for Arc Faults in Enclosed Double-Bus Assembly

Test Number	Rms Line Voltage Open Circuit	Arc-Voltage Crest Value From Test Line to Neutral (Volts)	Metallic Circuit Reactance × Ohms	Short-Circuit Current RMS Sym. Amperes Calculated	Short-Circuit Current RMS Sym. Amperes Test
18	300	146	0.00402	35,000	37,500
20	600	128	0.00352	95,000	99,000

Formulas for current, rms amperes per phase

$$i=-\frac{rv}{(r^2+x^2)}\times\left(1-\sqrt{1+\frac{(r^2+x^2)(E^2-v^2)}{r^2v^2}}\right) \quad (2)$$

The general formula 2 reduces to the simpler formula 3 when the resistance r of the metallic circuit is negligible.

Figure 5. Oscillogram of line-to-line arc voltages and total line currents

Shows arc voltages *A, C, E,* and total line currents *B, D, F,* for 3-phase short circuit initiated by 250,000-circular-mil bare copper cable placed across bare copper busses in double-bus test structure with metal enclosure (see figures 1–4 for test setup and connections). For test 18 at 300-volts rms 60-cycle open-circuit line-to-line voltage. For numerical values, see figure 6

$$i=\frac{\sqrt{E^2-v^2}}{x} \text{ amperes, when } r \text{ is negligible} \quad (3)$$

For simplified calculations, the current i in equation 2 may be expressed in terms of the bolted-fault short-circuit current, multiplied by a factor p which is a function of the ratio of v/E and the power factor $\cos\theta$ of the metallic impedance.

With the aid of curves of the factor p for particular values of the voltage ratio v/E and of $\cos\theta$, the calculation of short-circuit currents for arc faults becomes a simple procedure.

Results of calculations are given in table III. In these calculations the arc voltages observed in the tests were used together with the metallic circuit reactance based on bolted-fault tests. Calculated and observed short-circuit current values for the arc faults are in good agreement, considering that the test values include at least a small amount of d-c component. The calculated values obtained with the assumed sinusoidal form factor of 0.71 for the arc voltage are probably somewhat high since the arc voltage is generally flat-topped. Possibly a form factor of 0.8 or 0.85 for the arc voltages would be more nearly correct. The calculations of table III were made with a form factor of 0.71.

II. Arc-Fault Tests in Three-Conductor Cable

Short sections, approximately 4.5 feet long, of a three-conductor 350,000-circular-mil cable with varnished-cloth insulation, were provided with short-circuiting means including a number 17 short-circuiting wire placed in a hole (0.14 inch diameter) connecting two conductors, a twist drill (0.14 inch diameter) connecting two conductors, and $1^1/_4$-inch diame-

Table IV

Test No. 28—Cable-Fault Test on 350,000-Circular-Mil 3-Conductor Cable, Short-Circuited Between Phases 1 and 2 by a No. 17 Copper Wire Placed in a Drilled Hole $^1/_8$ Inch Diameter

Open-circuit line-to-line voltage:	300 volts rms
Available 3-phase short-circuit current:	43,100 rms sym. amp.
Peak current in cable fault: (triangular peak current limited by fault resistance)	14,000 amp. crest, in phases 1 and 2 only
Duration of short circuit:	0.006 sec.
Arc voltage in mid-region of short-circuit half cycle:	420 volts, mean value of flat top
Peak voltage at instant of current peak:	More than 800 volts (probably low due to magnetic oscillograph)

Results of test: The fault cleared itself with a fizzing sound. Contents of hole blown clear. All phases and sheath were found to be insulated from one another by test with a ringer. The same cable was used in the next test with a drill placed in the same hole

Crest current attained: 32 per cent of available rms symmetrical current

Table V

Test No. 29—Cable-Fault Test on 350,000-Circular-Mil 3-Conductor Cable. The Same Piece Tested in No. 28 Was Used Driving an 0.14-Inch Diameter Twist Drill Into Hole, Short-Circuiting Conductors 1 and 2. Voltage Was Applied to the Cable With the Drill in Place

Open-circuit line-to-line voltage:	600 volts rms
Available 3-phase short-circuit current:	98,600 amp. rms sym.
Peak current in cable fault: (minor current loop)	16,000 amp. crest in phases 1 and 2 only
Duration of short circuit	0.002 sec.
NOTE: This test not indicative of current-limiting action of fault since the circuit was closed on a minor loop of current of less than one-fourth-cycle total duration without abrupt current limitation, the maximum peak voltage across the fault being less than half of the phase-to-phase crest voltage	
Arc voltage (see note above):	200 volts max. peak
Results of test: The fault cleared itself with a fizzing sound. The drill was ejected from the hole	
Crest current attained: 16 per cent of available rms symmetrical current	

Table VI

Test No. 30—Cable-Fault Test on 350,000-Circular-Mil, 3-Conductor Cable. Short Circuit Initiated by Ramming a 1$^1/_4$-Inch Drill Resting Against the Cable, Into a Prepared Hole Between Phases 1 and 2 by a 20-Pound Weight Dropped on the Drill From a Height of 1 Foot Above It, After the Voltage Had Been Applied Across the 3 Conductors

Open-circuit, line-to-line voltage:	300 volts rms
Available 3-phase short-circuit current:	43,100 amp. rms sym.
Fault-current observations: Two faults occurred, the initial fault taking place at the instant voltage was applied to the circuit on account of very light contact or actual breakdown of gap. The fault cleared itself after 1.2 half cycle. The second fault occurred 21 cycles later when the drill was rammed into the hole by the weight and cleared itself after 1.3 half cycle	
First fault:	
Peak current	44,000 amp. crest in phases 1 and 2 only
Duration of current flow	1.2 half cycle
Arc voltage at current peak	Greater than 460 volts crest (off film)
Second fault:	
Peak current	52,000 amp. crest in phases 1 and 2 only
Duration of current flow	1.3 half cycle
Arc voltage at current peak	440 volts crest
Results of test: Two reports were heard. The drill was ejected, and the hole in the cable was materially enlarged by the explosions. Both faults were self-clearing	
Highest crest current attained:	120 per cent of available rms symmetrical current

ter spikes rammed into a prepared 1$^1/_4$-inch diameter hole between two of the conductors by a dropping weight, the latter short circuit resembling a pickaxe type of fault.

With three-phase voltage, of 300 or 600 rms line-to-line open-circuit volts, applied to one end of the samples from the generator and transformer equipment used in the other tests described here (see appendix), short circuits with available currents ranging from 43,000 to 98,000 rms symmetrical amperes (based on three-phase bolted fault tests) were produced, and the results summarized in tables IV–VII were obtained. They show:

(*a*). That a short circuit initiated by a fine wire in a small hole between phases limited the crest current to 14,000 amperes or 32 per cent of the available rms symmetrical current, with 300 volts open-circuit voltage,

(*b*). that short circuits initiated by forcing a 1$^1/_4$-inch diameter spike between two phase conductors resembling a pickaxe type of fault, gave currents ranging from 44,000 to 86,000 amperes crest or from 56 per cent to 120 per cent of the available rms symmetrical current,

(*c*). that the faults so obtained were self-clearing, interrupting the current within one or two half cycles,

(*d*). that short circuits initiated as two-conductor, phase-to-phase faults did not involve the third conductor, i.e., were interrupted as two-conductor faults.

III. Cable Impedance Tests

A. SHORT-CIRCUIT IMPEDANCE OF THREE-CONDUCTOR 350,000-CIRCULAR-MIL CABLE IN IRON CONDUIT

In these tests three-phase power was supplied to the three-conductor cable in a four-inch iron conduit, 100 feet long. At the far end of the cable a bolted three-phase short circuit was made. The test currents were in the vicinity of 15,000 amperes rms symmetrical at 60 cycles.

The cable and conduit specifications are stated in the appendix.

A comparison of test values of cable impedance in the iron conduit, with the calculated cable impedance in air, given in table IX, shows that the impedance in the conduit by test was 15 per cent higher than the calculated value for nonmagnetic surroundings. Similarly, the resistance increase and the reactance increase, due to the iron, by test were roughly 18 per cent and 12 per cent, respectively, over the calculated air values. The increases due to the magnetic conduit in these short-circuit tests, were within the range of values found in Brieger's[8] tests at normal load currents for three single-conductor cables held compactly and symmetrically in a triangle by suitable bonding within the iron conduit.

For single-conductor cables loosely placed within a magnetic conduit, greater increments of reactance and resistance, above the values for minimum triangular spacing in air, will be obtained, on account of the spreading of the conductors under action of the short-circuit forces.

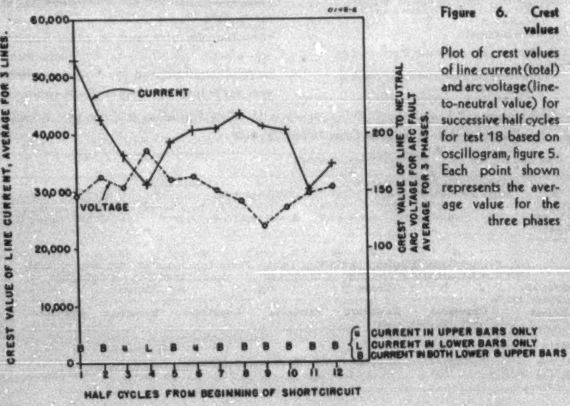

Figure 6. Crest values

Plot of crest values of line current (total) and arc voltage (line-to-neutral value) for successive half cycles for test 18 based on oscillogram, figure 5. Each point shown represents the average value for the three phases

B. CHECK TESTS OF IMPEDANCE OF THREE-CONDUCTOR CABLE IN AIR

The same three-conductor 350,000-circular-mil cable was also given a series of three-phase short-circuit impedance tests *in air*, with a bolted short circuit provided at the end of the 103-foot length of cable. The test results at currents of 3,800–15,000 amperes are tabulated in table X and are compared with calculated values based on the cable dimensions. From the table, it is seen that the air impedance values of the three-conductor cable by test agree closely with the calculated values, the differences being below five per cent for both resistance and reactance.

It is therefore concluded, that, as expected, the air impedance of the cables in question calculated from the available data applies with good accuracy at short-circuit currents in the absence of magnetic surroundings.

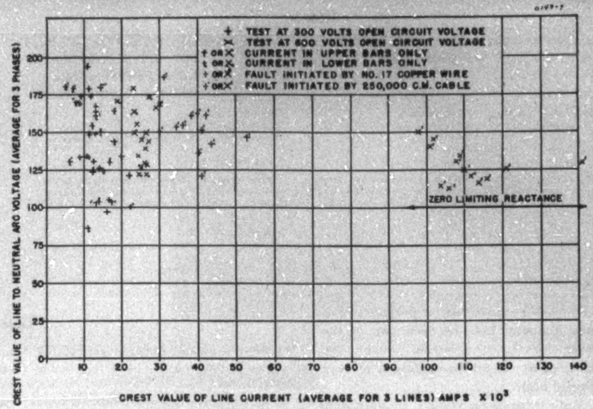

Figure 7. Crest values

Arc voltage versus short-circuit current for 3-phase 60-cycle short circuits initiated by loose conductors placed across bare copper busses in double-bus test structure with metal enclosure (see figures 1–4 for test setup and connections)

Table VII

Test No. 31—Cable-Fault Test on 350,000-Circular-Mil 3-Conductor Cable. Cable Hole Between Phases 2 and 3 Was Prepared Similar to That of Test 30 (Table VI). Short Circuit Was Initiated, as in the Preceding Test, by Ramming a Spike, Resembling the Point of a Pickaxe, Resting Against the Hole, Into the Cavity by a 20-Pound Weight Dropped on the Spike, From a Height of About 1 Foot, After the Voltage Had Been Applied to the Cable

Open-circuit line-to-line voltage:	600 volts rms
Available short-circuit current:	98,600 amp. rms sym.
Fault-current observations: The spike made its first contact with phases 2 and 3 after the circuit had been energized with voltage for 102 cycles. The fault cleared itself within one half cycle. Another fault occurred 15 cycles later, and lasted about one cycle, clearing itself. The explosion at the fault severed conductor 3 at the point of fault. After a further interval of 18 cycles, a third fault occurred between phases 2 and 3, which cleared itself within a half cycle. No further fault occurred during the remaining 16 cycles of the test	
First fault:	
Peak current	68,000 amp. crest, in phases 2 and 3 only
Duration of current flow	0.7 half cycle
Arc voltage at current peak	In excess of 850 volts crest; very sharp peak, not measurable accurately
Second fault:	
Peak current first half cycle	86,000 amp. crest, in phases 2 and 3 only
Peak current second half cycle	55,000 amp. crest, in phases 2 and 3 only
Arc voltage	No measurement
Duration of current flow	1.8 half cycle
Third fault:	
Peak current	73,000 amp. crest, in phases 2 and 3 only
Duration of current flow	0.8 half cycle
Arc voltage	No measurement
Results of test: Cable burst, phase conductor 1 remaining intact, conductor 2 grounded to sheath and was badly burned, conductor 3 separated	
Crest current attained:	From 56–87 per cent of available rms symmetrical current

IV. Impedance of Switchgear Conductor Assemblies and of Protective and Control Equipment

As one of the steps in preparing impedance data for engineering calculations of short-circuit currents in low-voltage circuits, various impedance tests were made to verify existing data and to supplement them. Accordingly, tests, as well as calculations in so far as practicable, were made for the impedance of various bar conductors in different arrangements, of air-circuit breakers, lever switches, current transformers and of other control equipment. Sections of complete commercial assemblies of low-voltage switchgear including a variety of these elements

Table VIII. Impedance of Three-Conductor Cable in Iron Conduit

Data and Results for One Set of Measurements

	2 RMS Line Currents	3 RMS Line Currents	4 RMS Line-to-Line Voltages at Input Terminals of Cable	5 RMS Line-to-Line Voltages at Input Terminals of Cable	6 Average Phase Impedance of 103-Foot Three-Conductor Cable at Five Degrees Centigrade (Ohms)	7 Average Phase Impedance of 103-Foot Three-Conductor Cable at Five Degrees Centigrade (Ohms)	8 Average Phase Impedance of 103-Foot Three-Conductor Cable at Five Degrees Centigrade (Ohms)	9 Phase Impedance of 1,000 Feet in Steel Conduit at 25 Degrees Centigrade (Ohms)	10 Phase Impedance of 1,000 Feet in Steel Conduit at 25 Degrees Centigrade (Ohms)	11 Phase Impedance of 1,000 Feet in Steel Conduit at 25 Degrees Centigrade (Ohms)
1 Test Number	Line in Which Current Was Measured	Magnitude and Phase of Current	Lines Between Which Voltage Was Measured	Magnitude and Phase of Voltage	Impedance	Resistance	Reactance	Impedance	Resistance	Reactance
	1	16 000/120	1–2	140/12						
2	2	15 600/0	2–3	141/258	0.00528/43	0.00386	0.00360	0.0534/41	0.0404	0.0349
	3	14 600/241	3–1	141/138						

were also tested at short-circuit currents, for over-all impedance determination.

As an example of the results of tests of assembled circuits, the data of table XI on the impedance of a section of metal-enclosed switchgear are given, the test values having been derived from oscillograph records. The circuit used was that of figure 9 comprising the following elements:

Item	Description	Length (Inches)	Center Spacing Between Phases (Inches)
a	2—5x$^1/_4$	24	6.5
b	2—5x$^1/_4$	14	6.5
c	2—5x$^1/_4$	23	9.5
d	2,000 amp air circuit breaker		
e	2—5x$^1/_4$	8	11
f	2—5x$^1/_4$	8	11
*g**	2—5x$^1/_4$	18	10
h	2—5x$^1/_4$	13$^1/_2$	7.25
i	2—5x$^1/_4$	40	7.25
j	copper angle 4x4x$^3/_8$	130	7.25

*Bars placed edge to edge in section *g*; face-to-face arrangement used in other sections.

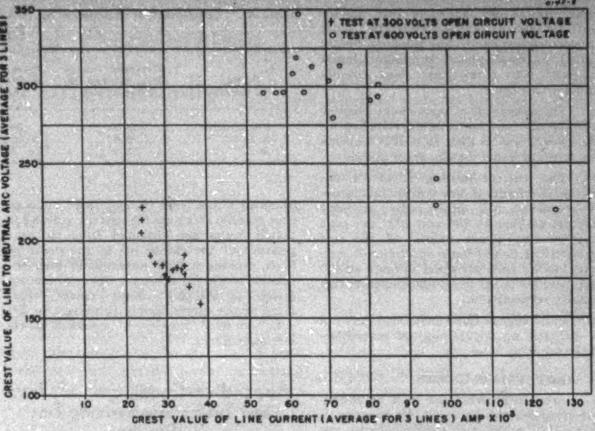

Figure 8. Crest values

Arc voltage versus short-circuit current in enclosed single-bus test structure. Short circuits initiated by loose conductors placed across bare copper busses

Calculated reactance values, also given in the table, are within ten per cent of the test values for the major portions of the assembly, the differences being somewhat higher for the smaller parts of the circuit.

The method and data used in the bar-conductor reactance calculations have been previously published.[5,6,7] As a first approximation in reactance calculations for bar assemblies with bends and loops, portions of the circuit having the same spacing and bar arrangement may be treated as if they were straight. Their combined reactance is then roughly equal to the sum of their separate lengths times the reactance per unit length for similar bars in a long straight circuit. The approximation results in reactance values somewhat too high (particularly when there are many short lengths between bends), but generally close enough for engineering calculations. To simplify calculations, curves of reactance per unit length for different bar arrangements may be drawn.

Table IX. Comparison of Impedance Results From Tests on 350,000-Circular-Mil Three-Conductor Cable in Four-Inch Iron Conduit With Calculated Data for the Same Cable in Air

1 Condition	2 Source From Which Value Is Obtained	3 Impedance Per 1,000 Feet at 25 Degrees Centigrade (Ohms) Impedance	4 Resistance	5 Reactance
Cable in iron conduit	Grand average of all tests	0.0538	0.039	0.037
Cable in air	Calculated from dimensions	0.0467	0.033	0.033
Ratio $\frac{\text{Cable in iron conduit, test}}{\text{Cable in air, calculated}}$		1.15	1.18	1.12

Table X. Results of Impedance Tests on Three-Conductor Cable in Air and Comparison With Calculated Values

1 Test Number	2 Location of Cable	3 RMS Line-to-Line Open-Circuit Voltage	4 Average RMS Phase Current for Three Phases	5 Average 60-Cycle Cable Impedance Per Phase for 103 Feet, Ohms Impedance	6 Resistance	7 Reactance
9	In air	100	3,800	0.0046		
10	In air	300	9,200	0.0045	0.0029	0.0035
11	In air	300	8,400	0.0045	0.0032	0.0032
13	In air	600	13,000	0.0048	0.0032	0.00355
Average impedance in air				0.00460	0.00310	0.00341
				Ohms Per 1,000 Feet		
Impedance of 1,000 feet at 25 degrees centigrade in air based on average *test* values above				0.0464/46	0.0325	0.0331
Impedance of 1,000 feet at 25 degrees centigrade in air *calculated* from dimensions				0.0467/45	0.033	0.033

In calculating the values of table XI the approximation described was used with the average conductor spacing between phases for each portion of the circuit, except that the circuit-breaker reactance, item *d*, was determined by separate test. The resistance of the bar conductors in question is negligible compared with their reactance and was therefore not included in the calculations.

In the current-transformer tests, not reported here, both wound and bar types were included. For the bar types the reactance at heavy short-circuit currents approached roughly that of the primary bar conductors.

With the necessary impedance data available, calculations of the impedance of low-voltage conductor and device assemblies are readily made and give results sufficiently close for short-circuit current calculations.

Summary and Conclusions

A. ARC FAULTS IN METAL-ENCLOSED BUS STRUCTURES TYPICAL OF MODERN LOW-VOLTAGE SWITCHGEAR

(1). The voltage drop at arc faults was found to be within the range from approximately 100 to over 300 volts crest, line-to-neutral value, at 300 volts and 600 volts rms open-circuit line-to-line voltages. Faults started as single-phase line-to-line faults developed into three-phase short circuits within a half cycle.

(2). The magnitude of short-circuit current taken by these arc faults at 600 volts line-to-line voltage was as high as 99,000 amperes rms, average value for the three phases.

(3). The current-limiting effect of accidental arc faults in low-voltage bus structures may be of a minor order, arc-fault currents as high as 88[*] and 100[*] per cent (average three-phase values) of the rms symmetrical bolted-fault short-circuit currents having been obtained in tests at 300 volts and 600 volts line-to-line, open-circuit voltage, respectively.

(4). Fault arcs in these structures may not be self-clearing within normal protective-device clearing time.

B. ARC FAULTS IN CABLES

(1). Arc faults produced in a three-conductor cable, not enclosed, by piercing it with a $1^{1}/_{4}$-inch diameter spike between two conductors gave currents as high as 80 per cent (approximate rms value) of the rms symmetrical bolted-fault short-circuit current, indicating that a large current-limiting effect (in excess of 20 per cent with respect to the rms symmetrical bolted-fault current) cannot be depended on.

(2). Short circuits caused by piercing cables with lighter metallic members resulted in currents limited to values well below half of the rms symmetrical bolted-fault short-circuit current.

(3). All of the cable faults in question were self-clearing within one or two half cycles.

C. CABLE IMPEDANCE

The impedance of a three-conductor 350,000-circular-mil cable in a four-inch iron conduit was 15 per cent higher than that obtained in nonmagnetic surroundings.

D. IMPEDANCE CALCULATIONS FOR SHORT-CIRCUIT CURRENT DETERMINATION

(1). Calculations of impedance for assembled switchgear circuits are in substantial agreement with test values at short-circuit currents.

(2). With the necessary impedance data available, calculations of the impedance of low-voltage conductor and device assemblies are readily made.

(3). The impedance of low-voltage circuits and the magnitude of short-circuit currents obtained in the tests reported here indicate that reliable short-circuit current values for bolted faults are obtained from the impedance of the circuit up to the point of fault, making it both unnecessary and unreliable to use (*a*) arbitrary discount factors applied to the short-circuit current calculated at the power-supply terminals, or (*b*) arbitrary fixed "maximum" values of short-circuit currents.

Table XI. Comparison of Impedance by Test With Calculated Reactance for Circuit Assembly Figure 9

Appendix—Conditions of Tests and Tables Summarizing Test Results

I. Fault-Arc Tests in Enclosed-Bar Structure

All the essential test conditions and details of test structure are shown in figures 1, 2, 3, and 4, except the dimensions of the metal enclosure which were

36 inches long, in the direction of the lower bars,
24 inches high,
20 inches wide, in the direction of the upper bars.

The sheet-steel walls, approximately one-eighth-inch thick, enclosed the bar assembly on five of the six sides, the sixth side, i.e., the side at which the lower bars entered the box, being left open. Braces of molded insulating material were used to support the bars in the box. The clearance between the unconnected ends of the bars and the metal walls was $1^{3}/_{4}$ inches, the metal enclosure being isolated from the electrical circuit, except that voltage-measuring devices were connected from the box to the bus bars.

Currents were measured not only in the power-supply conductors carrying the total line current, but also in each of the two branch connections *A* and *B* to the upper bars and lower bars respectively. By this means the duration of current flow in each of the busses could be determined.

EVALUATION OF ARC VOLTAGE AND CURRENT

Since the variations of line-to-line arc voltages were found to be relatively small, as indicated in the oscillograph record, figure 5, the mean[‡] crest value (in the center region of the half wave) was read for each half cycle of line-to-line arc voltage for which three-phase fault currents were flowing. In this manner three arc-voltage crest values—one for each phase—were obtained and were averaged for each of the successive half cycles. These voltages were then converted into line-to-neutral values by the approximate procedure of dividing by 1.732.

Crest values of current for the corresponding half cycles were then measured from the oscillograms, averaging in each case the three values for the three lines, using total line currents, regardless of whether there was current flowing in one or in both groups of bars.

A succession of crest values of fault voltage and of line current derived from the oscillogram of figure 5 is plotted for each half cycle in figure 6. From data similar to these the volt-ampere plot of figures 7 and 8 for the arc faults in the metal-enclosed bus assembly was prepared. A tabular summary of the fault voltage results is shown in table I. From these figures were derived the results for current-limiting effect in table II.

II. Cable-Fault Tests in Three-Conductor 350,000-Circular-Mil Cable

The cable tested was of the following description:

Conductor cross section, 350,000 circular mils
37 strands, each of 0.097 inch diameter bare copper, per phase
Conductor insulation, $^{7}/_{32}$ inch varnished cloth
Belt, $^{4}/_{32}$ inch varnished cloth
Lead sheath, $^{4}/_{32}$ inch thick

In the tests its sheath was isolated from the lines of the low-voltage test circuit. The essential test conditions are included with the test results in tables IV–VII.

III. Cable-Impedance Tests

The 350,000-circular-mil, lead-covered cable was of the same kind as that used in the cable-fault tests described above. It was 103 feet long, 100 feet of which was within a standard electrical conduit (iron) 4 inches inside diameter, and 4.5 inches outside diameter.

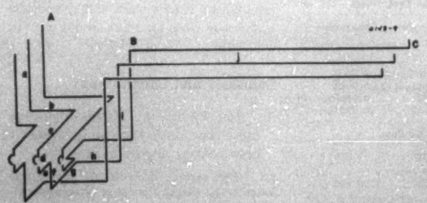

Figure 9. Circuit diagram of a section of switchgear circuit assembly

---

[*] For convenience, the average value, per phase, of the initial rms three-phase unsymmetrical short-circuit current for bolted faults may be taken as 1.25 times the rms symmetrical value. If the per cent values of arc-fault current are taken with respect to the average unsymmetrical bolted-fault current, as here approximated, they become reduced by the factor 1.25, or 70 and 80 per cent respectively.

Two New Methods of Accelerating Electric Motors Automatically

J. D. LEITCH
ASSOCIATE AIEE

Synopsis: The first of the two methods discussed in this paper is particularly applicable to a-c slip-ring motors. Series-resonance circuits responsive to the variation in rotor frequency with motor speed provide a means of accelerating the motor automatically, while a series-parallel resonance circuit similarly connected to the rotor can be used to protect the motor when "plugged" or suddenly reversed. The sensitive response of the latter circuit within a narrow frequency range makes possible its use as a "zero-speed" switch.

The second method has a more general application in that it can be used with any type of motor. A neon tube timing circuit measures the time intervals between the closures of accelerating contactors. One "timer" can be used for all steps of acceleration, with or without separate time adjustment. For a-c motor control, the introduction of a current transformer and a rectifying circuit makes possible the obtaining of time intervals which are increased automatically with increase in motor load. Such a scheme is often referred to as "time-current" acceleration in order to distinguish it from "constant-time" acceleration where the time interval is independent of the load.

Introduction

If full voltage is applied to an electric motor at rest the current will be excessively large, and there is a likelihood that the resultant forces will damage both the motor and the mechanism connecting it to the load. This is true of d-c motors in particular and, to a lesser degree, of a-c motors. It is necessary, therefore, to limit the "inrush" current during the starting period, and for d-c motors this is done by inserting resistors in series with the armature. Series resistors, series reactors or autotransformers are connected in the primary circuit for a-c motors, unless the a-c motor is of the wound-rotor induction type in which case it is customary to limit the primary current by connecting resistors in the secondary or rotor circuit external to the motor itself.

As the motor attains speed a counter electromotive force is generated which reduces the current, and if adequate torque is to be maintained the current-limiting means must be gradually removed from the circuit. This may be done either manually, by means of the usual drum or face-plate type of controller, or automatically, by means of relays controlling electromagnetic contactors. For many years the trend has been more and more toward fully automatic magnetic controllers, so that manual controllers are now rarely used in steel mills and similar industries.

The following is a brief review of some of the common automatic methods now in use.

(1). Counter-Electromotive-Force Method

When a d-c motor is accelerated, the back-electromotive force induced at the armature terminals is a function of the speed of the motor. If a series of relays are connected in parallel across the armature, the voltage applied to these relays will increase as the motor accelerates. If each relay is designed to operate at a definite voltage, it is obvious that such a scheme provides a means of short-circuiting the current-limiting resistance in successive steps in accordance with the speed of the motor. This method is generally confined to d-c motor control.

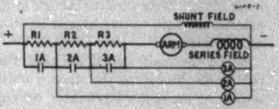

Figure 1. Counter-electromotive-force method

Figure 1 shows how the counter elec-

Paper 40-142, recommended by the AIEE committee on industrial power applications, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted June 13, 1939; made available for preprinting August 13, 1940.

J. D. Leitch is engineer in charge of development for The Electric Controller and Manufacturing Company, Cleveland, Ohio.

Oscillograph measurements were made of line current and of the three line-to-line voltages at the power-supply end of the cable. In all tests the lead sheath was kept isolated from the circuit.

Method of Evaluating Impedance

The impedance magnitude was determined from the ratio of

$$\frac{\text{(average rms line-to-line voltage for 3 phases)}}{1.732\ \text{(average rms line current for 3 lines)}}$$

the line-to-line voltages being measured at the input end of the cable. Phase angles of voltages and currents were measured with respect to the phase of a reference current. The impedance-phase angle, used for evaluating the resistance and reactance components, was then obtained from the average phase-angle difference between line-to-line voltages and corresponding line currents, adding 30 degrees to allow for the phase difference between line-to-line and line-to-neutral values.

In these tests there were no appreciable distortions of wave shape, so that the rms values could be calculated by dividing the measured crest values by 1.414.

Impedance values of the three-conductor cable in the iron conduit and the test data on which they were based are given in table VIII for one set of measurements. The cable impedance per 1,000 feet, in the last three columns was derived from the test values, for 103 feet of cable in columns 7, 8, and 9.

In table IX, the reactance for the cable in air was calculated from the dimensions of the conductors and their spacing using the conventional formula as given in handbooks.

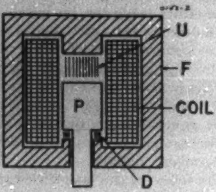

Figure 2. Series lock-out relay

tromotive force method is applied to a compound-wound motor. It will be noted that the voltage across the relays $1A$, $2A$, $3A$ during the accelerating period is $V-RI$, where V = line volts, I = armature current, and R = resistance between the positive side of the line and the relay connection. This permits the use of accelerating relays having almost identical characteristics.

When the main switch is closed, current flows through all the starting resistance. As the motor accelerates, the current decreases and the voltages applied to the relays increase until relay $1A$ closes, short-circuiting the first step of resistance R_1. The current increases immediately, applying greater torque to the motor and causing further acceleration. Again as the motor gains speed, the voltage across relay $2A$ increases until it closes, short-circuiting resistance R_2. This is repeated until the last acceleration contactor closes and the motor is connected directly across the line.

(2). Series Lock-Out Method

The series lock-out method has essentially the same characteristics as the counter electromotive force method inasmuch as each acceleration contactor closes after the motor has reached a definite speed. The accelerating relay itself merits description.

Referring to figure 2, the action of the relay is as follows. For very heavy current, the narrow portion of the plunger P is magnetically saturated so that considerable flux crosses the air-gap D. This causes a downward pull which, when added to the weight of the plunger, overcomes the upward pull through the air-gap U. As the current decreases, less flux crosses the air-gap D and the upward pull becomes sufficient to lift the plunger. Thus the relay remains open for heavy currents, closes for lower values, and opens again for still lower values.

Figure 3 shows the application of such a relay to a d-c motor. When the main line switch closes, current flows through the armature, limiting resistors and the first accelerating relay, $1A$. The relay ampere-turns are such that the plunger is magnetically saturated and the relay is held open. When the current falls to a definite value the plunger is pulled up, moving a contact-making mechanism which short-circuits the first resistance step R_1. This causes the current to pass through both $1A$ and $2A$ relay coils, relay $1A$ remains closed, but $2A$ will not close until the current again falls to its operating value. The operation is repeated until relay $3A$ closes, short-circuiting all the resistance as well as the series coils in all the relays. Relays $1A$ and $2A$ open, but $3A$ remains closed because of its additional shunt winding connected across the motor.

A similar relay has been used for automatic acceleration of a-c motors, placing it either in the primary or secondary circuit. Difficulties inherent in a-c relay design make it not nearly so satisfactory as the corresponding d-c relay.

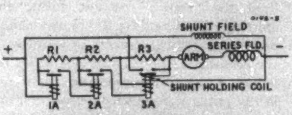

Figure 3. Series lock-out method

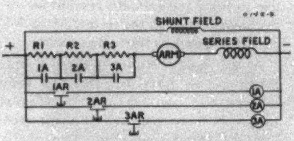

Figure 4. Constant-time method. Dashpot relays

The above methods are particularly suited to motors connected to heavy inertial loads, since the acceleration contactors will not close too quickly at any time. That is, the time interval between closure of acceleration contactors depends entirely upon the load. It often happens, however, especially in steel mills, that motors are overloaded with frictional loads and if any of the above types of control were used, the motor might remain "stalled" indefinitely. For such conditions it is necessary to provide "forced acceleration" so that the acceleration contactors will ultimately close, irrespective of the load.

Another disadvantage of the series lock-out method appears frequently with very lightly loaded motors, since the motor speeds up more rapidly than the accelerators close so that by the time the last acceleration relays are ready to close, the current has fallen to such a low value that the relays will not operate. This would leave some or all of the series resistance in the circuit.

(3). "Constant-Time" Method

The "constant-time" method gives acceleration intervals which are independent of the load on the motor. All that is necessary is some electrical or mechanical means of delaying the closure or opening of electrical contacts. Many schemes are now in use, such as dashpots or escapement mechanisms connected mechanically to the acceleration contactors, or motor-driven cams which operate a series of contacts in sequence.

The application of individual dashpot relays, mechanically connected to the accelerating contactors, is shown in figure 4. The $1AR$ relay is connected to the main line contactor, the $2AR$ relay to the $1A$ contactor, and the $3AR$ relay to the $2A$ contactor. When the main line contactor (not shown in the diagram) is open it holds the $1AR$ relay plunger down against a compression spring. Upon closure of the contactor the plunger is forced upward against the resistance offered by the fluid within the dashpot. After a definite time interval the plunger reaches its upper position and closes the relay contacts which permit the acceleration contactor $1A$ to close. The operation is repeated with each of the other relays in sequence until all of the current-limiting resistance has been short-circuited.

One decided disadvantage of the "constant-time" method becomes apparent when very heavy loads are encountered, in that the acceleration contactors will close before the motor attains any appreciable speed and the resulting excessive currents may cause considerable damage. Nevertheless, "constant-time" accelera-

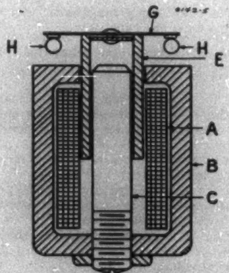

Figure 5. Time-current relay

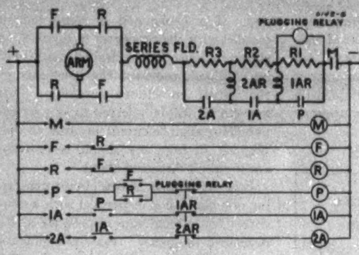

Figure 6. Time-current method. Plugging, reversing controller

tion has found favor because of its simplicity and the fact that it provides "forced acceleration." It has the added advantage of being equally applicable to a-c and d-c motors.

(4). "Time-Current" Method

In the "time-current" method, as the name implies, the acceleration intervals are modified by the current flowing in the motor. This method, which so far has been used in the control of d-c motors only, has all the advantages of the "constant-time" method, along with the added advantage that the time intervals between acceleration steps are automatically increased with increase in load.

A rather interesting example of a "time-current" relay is shown in figure 5. It is fundamentally a series relay with normally closed contacts. The iron structure *B* surrounding coil *A* provides a path for the magnetic flux. An iron core *C* passes through the center of the coil, its position being adjustable by means of screw threads. A movable aluminum sleeve *E* is suspended between the core and the coil. A bridge contact arm *G*, which normally rests on the two fixed contacts *H*, is fastened to the upper end of the aluminum sleeve. The initial inrush of current through the coil, which is connected in series with the motor armature, causes the aluminum sleeve to be repelled upward out of the coil. (The sleeve behaves like a short-circuited secondary winding and, by Lenz' law, the currents set up in it produce a magnetic field in opposition to that produced by the coil.) As long as the current is rapidly changing, the aluminum sleeve will experience an upward thrust, but as the current approaches a steady, or nearly steady, state the sleeve begins to fall under the action of gravity. As it falls, it cuts the main magnetic flux between the frame and the upper end of the core and therefore will fall at a rate which depends upon the current flowing in the coil: the higher the current, the slower the rate. In this way the length of time the relay contacts remain open depends upon the load on the motor. The relay will always close its contacts, however, to provide "forced acceleration."

Figure 6 shows a d-c plugging, reversing controller in which "time-current" relays of the above design are used. If the master is moved to the point 2*A* in a forward direction, contactors *M* and *F* will close immediately. With the motor initially at rest, the closure of *F* completes a circuit to the plugging contactor coil *P* through the plugging relay contacts, which do not open under these conditions. When *P* closes, its normally open auxiliary contacts close to provide a circuit to the 1*A* contactor. Contactor 1*A* cannot close, however, until the acceleration relay 1*AR* closes. When 1*A* closes, resistance R_2 is short-circuited and current flows through relay 2*AR*, causing it to open its contacts. After a second time interval contactor 2*A* will close, applying full voltage to the motor.

The plugging relay has a shunt winding connected across the plugging resistance R_1. Upon sudden reversal of the voltage applied to the motor when running in the forward direction, the voltage across R_1 becomes greater than it was when starting the motor from rest, so that the plugging relay opens its normally closed contacts and prevents the closure of the plugging contactor *P* until the motor has been brought to rest. In this way additional protective resistance is added to the armature circuit during the period of excessively high voltage, that is, when the motor is "plugged."

In the foregoing, acceleration methods which utilize the variation in frequency of rotor currents with speed of a wound-rotor induction motor or which provide "time-current" acceleration of a-c motors have not been considered. The new methods about to be described cover these two cases.

Method I—Automatic Acceleration of Wound-Rotor Induction Motors

It can be shown readily that the voltage across the external phase resistance R_E connected to a three-phase wound-rotor induction motor is given by

$$V_2 = \frac{sE_2R_E}{\sqrt{3}\sqrt{s^2X_0^2+(R+R_E)^2}} \tag{1}$$

where

s = rotor slip
E_2 = open-circuit rotor voltage across rings
X_0 = standstill rotor reactance per phase
R = rotor resistance per phase

Figure 7 shows how this voltage varies with slip for different values of R_E. In plotting the curves, the constants in equation 1 were those of a typical 20-horsepower, 220-volt motor in which R = 0.1 ohm, X_0 = 0.5 ohm and E_2 = 220 volts. For lower frequencies (higher motor speeds) the voltage is nearly proportional to the slip. This is particularly true for

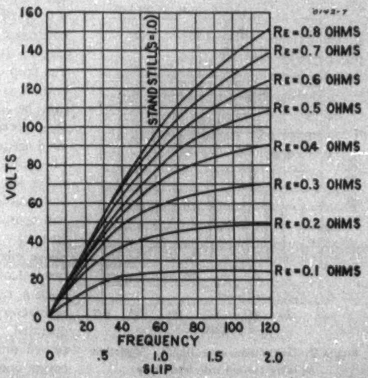

Figure 7. Variation in rotor voltage with frequency

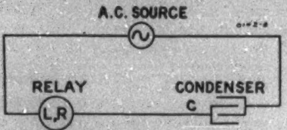

Figure 8. Series resonance circuit

greater values of R_E. In practice R_E is large when the motor is being plugged or started from rest and is small only when it has gained considerable speed. Thus for practical purposes the proportionality between V_2 and s will hold approximately over the entire range of frequencies ($s=0$ to 2). This proportionality will be assumed in the following discussion of relay circuits which might be used to provide automatic acceleration.

Consider a circuit consisting of a simple electromagnetic relay, the impedance of which is predominantly reactance. If such a relay is connected to a source of alternating potential difference proportional in magnitude to its frequency, the current in the relay will remain practically constant and independent of frequency. Obviously such a relay would not be responsive to motor speed and hence would be unsuitable for acceleration purposes.

If, however, a condenser is connected in series with the relay as in figure 8, the impedance of the circuit will be given by

$$|Z|=\sqrt{\left(\omega L-\frac{1}{\omega C}\right)^2+R^2} \tag{2}$$

where L and R are the inductance and resistance of the relay, C the capacity of the condenser, and $\omega=2\pi\times$frequency. When $\omega L=1/\omega C$ the impedance is a minimum and the circuit is said to be in resonance with the supply frequency. For frequencies greater than that of resonance ($\omega L>1/\omega C$) the impedance will be determined mainly by the reactance of the relay, while for lower frequencies ($\omega L<1/\omega C$) the impedance is approximated by the capacitance of the condenser. In the region close to resonance the resistance R determines the impedance.

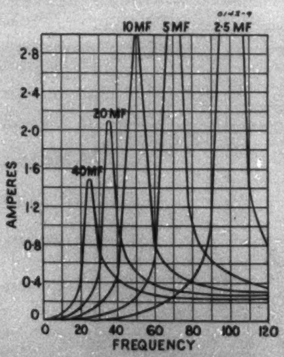

Figure 9. Series resonance circuit. Variation in relay current with frequency

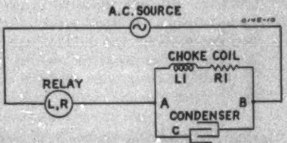

Figure 10. Series-parallel resonance circuit

If a voltage having a magnitude proportional to its frequency is applied to the above circuit, the current will increase as the square of the frequency for frequencies well below that of resonance, reaching a maximum at the point of resonance. Thereafter the current will decrease, approaching a steady value. Figure 9 shows this variation in current with frequency for different values of C. In plotting these curves a voltage equal to 1.5 times the frequency was employed and L and R were assumed equal to 1.0 henry and 25.0 ohms respectively.

By connecting a series of such relay circuits across the secondary resistance of a wound-rotor induction motor, it is possible to provide automatic acceleration at intervals determined by the motor speed. Similarly the circuit may be used to provide plugging protection in the following manner. Using a relay having a "pick-up" current twice its "drop-out" value and supposing the drop-out current to be 0.13 ampere, then with a 2.5-microfarad condenser in the circuit the relay would pick up at 75 cycles or higher frequency and drop out at 60 cycles. If closer operation is required the condenser size may be increased slightly to bring the steep portion of the curve nearer the desired frequency of operation. The applied voltage may be reduced accordingly.

For some motor-control applications it is desirable to have a relay means which will operate within still closer limits of frequency than that provided by the above circuit, and which will be independent of small changes in line voltage. Such a relay means would prove more satisfactory than any of the mechanically operated "zero-speed" switches now employed and might be used to give accurate operation in plugging a motor to rest. If a choke coil is connected in parallel with the condenser in figure 8, as shown in figure 10, the desired result may be obtained, provided the constants of the circuit are chosen carefully. This new circuit will be referred to as a series-parallel resonance circuit in order to distinguish it from the simple series-resonance circuit discussed above.

It is well known that a circuit consisting of a choke coil in parallel with a condenser has a maximum impedance at its resonance frequency. For "plugging-to-stop" service and for zero-speed relay purposes a rapid change in relay current must occur in the region of line frequency, therefore the line frequency f_0 might be chosen as the resonance frequency of the parallel or "tank" circuit AB in figure 10. Using the equation derived from this condition, the necessary relationship between the constants which will give a minimum impedance to the total circuit at a frequency just above f_0 may be approximated as follows:

Admittance of "tank" circuit $AB=$

$$\frac{R_1-j\omega L_1}{R_1^2+\omega^2L_1^2}+j\omega C \tag{3}$$

Impedance of "tank" circuit $AB=$

$$\frac{(R_1^2+\omega^2L_1^2)(R_1-j[\omega CR_1^2+\omega^2L_1^2C-\omega L_1])}{R_1^2+(\omega CR_1^2+\omega^2L_1^2C-\omega L_1)^2}$$

Impedance of total circuit $Z=R+j\omega L+$ (impedance of AB)

whence

$$|Z|=\sqrt{\left[R+\frac{R_1(R_1^2+\omega^2L_1^2)}{R_1^2+(\omega CR_1^2+\omega^2L_1^2C-\omega L_1)^2}\right]^2+\left[\omega L-\frac{(R_1^2+\omega^2L_1^2)(\omega CR_1^2+\omega^2L_1^2C-\omega L_1)}{R_1^2+(\omega CR_1^2+\omega^2L_1^2C-\omega L_1)^2}\right]^2} \tag{4}$$

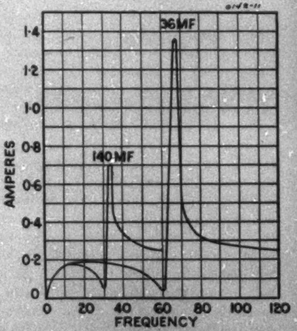

Figure 11. Series-parallel resonance circuit. Variation in relay current with frequency

Since a choke coil can be designed in which R_1 is much less than $\omega_0 L_1$ where $\omega_0 = 2\pi f_0$ and f_0 is as low as 30 cycles, equation 3 may be replaced by the approximation

$$\text{Admittance of } AB \approx \frac{R_1}{\omega^2 L_1^2} - j\left(\frac{1}{\omega L_1} - \omega C\right) \tag{3a}$$

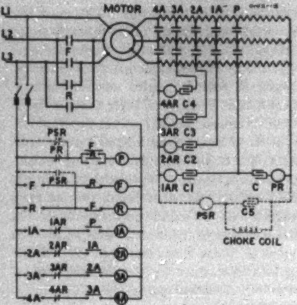

Figure 12. Frequency method. Plugging, reversing controller

This admittance will be a minimum (or its reciprocal, the impedance a maximum) when $\omega^2 = 1/L_1 C$ and for this to occur at frequency f_0 we have

$$\omega_0^2 = \frac{1}{L_1 C} \tag{5}$$

Using the approximation $3a$ the impedance of the total circuit may be written

$$Z \approx \frac{\dfrac{R_1}{\omega^2 L_1^2} + j\left(\dfrac{1}{\omega L_1} - \omega C\right)}{\dfrac{R_1^2}{\omega^4 L_1^4} + \left(\dfrac{1}{\omega L_1} - \omega C\right)^2} + R + j\omega L$$

Assuming $\dfrac{R_1^2}{\omega^4 L_1^4} \ll \left(\dfrac{1}{\omega L_1} - \omega C\right)^2$ in the region where $\omega = 2\pi f_1$, an assumption which can be verified for any particular case, the total impedance reduces to

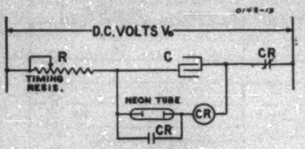

Figure 13. Neon tube timing circuit

$$Z \approx R + j\omega L + \frac{\dfrac{R_1}{\omega^2 L_1^2}}{\left(\dfrac{1}{\omega L_1} - \omega C\right)^2} + j\left(\frac{1}{\dfrac{1}{\omega L_1} - \omega C}\right)$$

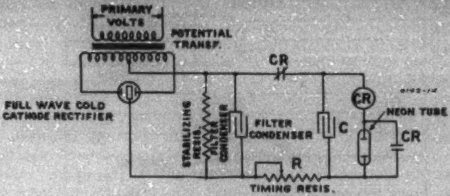

Figure 14. Constant-time timer

but C must be chosen to meet condition 5 hence

$$Z \approx R + j\omega L + \frac{\dfrac{R_1}{\omega^2 L_1^2}}{\left(\dfrac{1}{\omega L_1} - \dfrac{\omega}{\omega_0^2 L_1}\right)^2} + j\left(\frac{1}{\dfrac{1}{\omega L_1} - \dfrac{\omega}{\omega_0^2 L_1}}\right)$$

and for this to be a minimum at frequency f_1 we have

$$\omega_1 L + \frac{1}{\left(\dfrac{1}{\omega_1 L_1} - \dfrac{\omega_1}{\omega_0^2 L_1}\right)} = 0$$

or

$$\frac{\omega_1^2}{\omega_0^2} = 1 + \frac{L_1}{L} \tag{6}$$

Equations 5 and 6 give the relationships that must exist between L, L_1, C, f_0, and f_1 so that the circuit will have a much higher impedance at frequency f_0 than at f_1. Assuming $f_1 = 1.1 f_0$ and using the same relay as before where $L = 1.0$ henry and $R = 25$ ohms, then $L_1 = 0.2$ henry. For $f_0 = 30$ cycles, C takes the value 140 microfarads and for $f_0 = 60$ cycles, $C = 36$ microfarads.

Since no difficulty is presented in designing a choke coil having an inductance of 0.2 henry and a resistance as low as 2.0 ohms, the two assumptions $R_1 \ll \omega_0 L_1$ and $\dfrac{R_1^2}{\omega_1^4 L_1^4} \ll \left(\dfrac{1}{\omega_1 L_1} - \omega_1 C\right)^2$ are now justified for as low as 30 cycles per second. Using all of these constants in equation 4 to determine the variation in impedance of the total circuit with frequency and assuming a voltage equal to 1.5 times its frequency applied to the circuit, the relay current was calculated and plotted in figure 11.

An experimental relay requiring a pick-up current approximately twice its drop-out value was designed along with a choke coil in accordance with the above constants. With the relay adjusted to drop out at 60 cycles, it picked up at 61.5 cycles thus providing the desired operation. Because of the steepness of the current curve (figure 11) between 60 and 66 cycles the operation of the relay was not affected appreciably by a ten per cent variation in line voltage.

The complete wiring diagram of a plugging, reversing controller for a wound-rotor induction motor is shown in figure 12. The controller provides four steps of acceleration as well as plugging protection. Alternatively the controller becomes a four-step starter with plugging-to-rest feature if the series resonance circuit containing relay PR is replaced by a series-parallel resonance circuit containing relay PSR as shown in the diagram. The operation of the controller is as follows.

With motor at rest, suppose the master switch is moved to the point $4A$ in the forward direction. Contactor F closes to apply "forward" power to the motor primary and complete a circuit through its normally open auxiliary contacts to the plugging contactor coil P. Contactor P closes since the plugging relay PR does not open its normally closed contacts under these conditions. The normally open auxiliary contacts on P close to prepare a circuit for the coil of acceleration contactor $1A$ which, however, is not energized until relay $1AR$ opens, closing its normally closed contacts. Similarly, when the acceleration contactor $1A$ closes it prepares a circuit for the $2A$ contactor, which closes after the $2AR$ relay opens. The operation is repeated automatically as the motor accelerates until finally the last acceleration contactor closes, short-circuiting the entire secondary resistance.

Suppose the motor is running in the forward direction and the master switch is removed quickly to the last point reverse. The F contactor will open and R will close, applying reverse power to the motor primary. The frequency in the secondary will now be greater than line frequency and the plugging relay PR will close, opening its normally closed contacts and preventing the closure of contactor P. Near the instant at which the motor comes to rest, relay PR will open and contactor P will close to remove the plugging resistance from the motor secondary. The motor will then accelerate automatically in the reverse direction in a manner similar to that described above.

Figure 15. Neon tube method. Multistep a-c starter

Referring to the alternative connections for a starter, suppose the motor is running in the forward direction and it is desired to bring it to rest quickly. All that is necessary is to move the master switch to any of the reverse points, returning it to the "off" position immediately after the *R* contactor closes. Closure of *R* increases the secondary frequency, causing the plugging-to-stop relay *PSR* to close, closing its normally open contacts to provide a holding circuit for the *R* contactor against return of the master to the "off" position and, at the same instant, opening its normally closed contacts to prevent the closure of the plugging contactor *P*. When the motor comes to rest relay *PSR* opens and the *R* contactor drops out, removing power from the primary.

All the relay means described in the foregoing have been made to operate satisfactorily in close agreement with calculated results. Failure to provide forced acceleration by this method of control is not a disadvantage in the case of a wound-rotor induction motor, since it is possible to adjust resistance values in the secondary so that maximum torque is applied at every step of acceleration.

Method II—"Constant-Time" and "Time-Current" Acceleration of A-C and D-C Motors

The frequency relay method just described bears the same relationship to a-c motors as the counter electromotive force method does to the acceleration of d-c motors in that the acceleration contactors close at intervals determined by the speed of the motor. In fact this property is common to all methods based on the current-limit principle as distinguished from those which operate on the time-limit principle, where the contactors close at intervals independent of the motor speed.

While current-limit methods have many important applications, it is generally considered that time-limit acceleration has the wider use. The most frequently used timing devices are dashpot relays (one for each step of acceleration) and motor-driven cam-operated switches. Dashpot relays require careful maintenance and, because of their limited range of adjustment, are not suited to the acceleration of heavy inertial loads since they necessitate an excessive number of acceleration steps. Motor-driven timing devices, on the other hand, do not lend themselves to rapid adjustment in the field and are relatively expensive. In view of these disadvantages it is desirable to use a timing device which operates on electrical principles only and is readily adjustable over a wide range. Such a method will now be described.

When a constant d-c voltage V_0 is applied to a circuit consisting of a resistance R in series with a condenser of capacity C, the voltage V across the condenser at any time t after closing the circuit is given by

$$V = V_0(1-e^{-t/RC}) \qquad (7)$$

If a neon glow-discharge tube is placed across the condenser it will "fire" at the instant the voltage on the condenser reaches the ignition potential of the tube. The time required for the voltage V to reach this potential, V_1 say, is propor-

Figure 17. Neon tube method. Plugging, reversing d-c controller

tional to the product RC and, for a fixed condenser, to R only. Thus a simple and accurate method of timing is provided in which the time interval may be adjusted over any desired range. This method has been used successfully and extensively during the past seven or eight years in timing resistance welders.

Figure 13 shows a control relay CR connected in series with the neon tube in the above circuit. The relay has normally open and normally closed contacts. At the instant the tube fires, the relay closes opening its normally closed contacts to disconnect the timing circuit from the charging voltage V_0. The normally open contacts close to short-circuit the neon tube and provide a holding circuit for the relay against the extinction of the tube. By proper choice of the relay coil it is possible to assure complete, or practically complete, discharge of the condenser, a condition essential to the consistent operation of the timer.

Assuming the extinction potential of the tube to be V_2, the amount of energy given up by the condenser in discharging from V_1 to V_2 is $\frac{1}{2}C(V_1^2-V_2^2)$. This energy must be greater than that required to close the relay CR; otherwise, positive operation will not be obtained. With a 20-microfarad condenser, a tube having an ignition potential of 160 volts and an extinction potential of 80 volts permits the use of a relay sufficiently rugged to be mounted on the same panel as an 800-ampere a-c contactor.

It is always important in automatic motor control work to investigate the effect of variation in line voltage on the acceleration time intervals. If V_0, the voltage applied to the timing circuit, is proportional to the line voltage, it is obvious from equation 7 that the time intervals will decrease or increase as the line voltage is higher or lower. This compensation is in the desired direction.

Application to A-C Motors

In applying the above timing scheme to a-c motors, a source of d-c potential is necessary. This may be obtained by using an ordinary radio rectifying system as shown in figure 14. The transformer has a high-voltage winding, giving 700 volts, while low-voltage windings are available for the range 110 to 550 volts. A cold cathode rectifier is used in preference to the usual '80 tube, since it is free from the time-lag inherent in hot cathode tubes and eliminates the need of control wiring and relays for the filament. The 50,000-ohm permanent load resistor holds the d-c voltage within close limits when the impedance of the timing circuit is varied.

The wiring diagram for a multistep starter is shown in figure 15; its operation is as follows. When the push button is closed, relay P closes to form its own holding circuit against the opening of the button and to complete a circuit to the M contactor coil. The primary of the timing transformer is energized through the normally closed auxiliary contacts on the last acceleration contactor. After a definite time the CR relay operates, closing relay A which, in turn, closes the $1A$ contactor. Relay A forms its own holding circuit against the opening of the normally closed contacts on contactor $1A$, so that A will remain closed as long as CR is closed. Contactor $1A$ forms its own holding circuit against the opening of relay A; therefore it is necessary only that CR remain closed long enough to let contactor $1A$ close. Closure of A opens its normally closed contacts in series with relay B, so that relay B cannot close until A opens and, since A opens only after CR has opened, the $2A$ contactor cannot close until the second time interval has been measured by the timer. The operation is repeated for each step of acceleration until finally the last acceleration contactor closes, disconnecting the timer from the line.

While a wound-rotor induction motor was chosen in the above illustration, any type of a-c motor would have served equally well. One timer only was used for all steps of acceleration, and although not shown in the diagram and usually unnecessary in practice, each step could have been provided with its own timing resistance.

The foregoing acceleration method provides time intervals which are constant and independent of the load on the motor. Time-current acceleration may be provided by the addition of a current-transformer and a second rectifying system connected as shown in figure 16. The rectified voltage from the current transformer is connected in opposition to that from the potential transformer, so that the heavier the load on the motor the lower the voltage applied to the timing circuit and the longer the time intervals. The potentiometer shown across the d-c output from the current transformer provides a means of adjusting the time-current effect to suit load conditions.

Application to D-C Motors

A constant-time, plugging, reversing controller for a series-wound d-c motor is shown in figure 17. When the plugging contactor P closes, its normally open auxiliary contacts close completing a circuit to the timer. After a definite time interval, relay CR closes energizing relay A. Relay A forms its own holding circuit and completes another circuit to contactor $1A$. It is essential that relay CR opens before contactor $1A$ closes, otherwise relay B and contactor $2A$ would close before the second time interval had elapsed. In other regards the controller operates in much the same way as those described elsewhere.

Time-current acceleration may be obtained by placing a potentiometer across the starting resistance and connecting its central tap to the timing circuit. In adjusting the position of the central tap, care must be taken that the voltage applied to the timing circuit is always well above the ignition potential of the neon tube, a condition which limits the amount of time-current effect which can be obtained in this way.

While no practical limitation is inherent in the "neon time" method of acceleration which would prohibit its use for lightly loaded motors, it is finding its widest application in the acceleration of heavily loaded motors requiring long-time intervals.

The Use of Auxiliary Impedances in the Single-Phase Operation of Polyphase Induction Motors

RAYMOND W. AGER
ASSOCIATE AIEE

RECENT literature indicates a considerable interest in the subject of single-phase induction motors which use split-phase starting. In the available motors condensers are often used as auxiliary impedances in the starting circuit and may also be used in the running circuit. Much of the existing literature on these machines deals with the condenser required and the torque developed. For the purposes of this analysis ideal conditions of balancing will be assumed. If the auxiliary impedances are properly chosen the motor windings will be subjected to balanced polyphase voltages. Under these conditions the motor will operate as a polyphase motor and the analysis may be carried out using standard polyphase motor theory and a-c circuit theory. The first machines analyzed will be of symmetrical two- and three-phase design. Following this, motors having unsymmetrical windings will be considered. Some observations on the related subjects of motor size and motor rating will also be included.

Motor Characteristics

In order that the analysis might be made throughout the entire speed range of the motors, the complete motor characteristics were determined from assumed circle diagrams. First a low resistance motor having the characteristics shown in figure 1 was assumed. By doubling the rotor resistance of this motor the characteristics of a high-resistance motor were obtained and are shown in figure 2. The same characteristics have been assumed for two-phase and three-phase machines although this results in slightly different horsepower ratings. In the final tabulations where comparisons were desired the values have been corrected for this difference. In calculating the impedances and the condenser capacitances a line voltage of 100 has been assumed.

Method of Analysis

If a polyphase motor is operated from a single-phase line, and auxiliary impedances are used to shift the phase currents and the motor terminal voltages so that the currents and voltages of the motor are properly balanced both as to phase and magnitude, the motor will operate as though it were supplied from its normal polyphase line. Due to the fact that the motor current and power factor both change as the speed changes, the impedances required also must change with the motor speed. If these changes in the balancing impedances are small so that average values may be chosen which will reasonably approximate the ideal values over a range of speed, then, by using these average values, approximate polyphase performance may be obtained over this speed range with the motor operated from single-phase lines. If the auxiliary impedances required should change radically in value or change in character, then the choice of auxiliary impedances must rest upon other considerations and fixed values of these impedances cannot be expected to give single-phase performance equivalent to the polyphase performance over the speed range, although, it may be possible to have the two performances equal at some speed within the range. This study of the impedance variations was made with the idea that general conclusions regarding these impedances might be drawn. The number of auxiliary impedances considered has been limited to two for each connection, with one of these two assumed a perfect condenser.

Three-Phase Motors

The first motors considered will be of three-phase design. These may be balanced by two different methods. The first method is by series impedances and has been called type *A*. The second method is by shunt impedances and has been called type *B*. Type *A* connection is shown in figure 3, which also shows the vector diagram. From the geometry of the vector diagram it may be seen that Z_A is a perfect condenser, while Z_B is a resistance. The numerical values of these impedances may be found from the following formulas.

$$Z_A = -j\frac{E(1.732 \sin \theta - \cos \theta)}{I}$$

$$Z_B = \frac{E(\sin \theta - 1.732 \cos \theta)}{I}$$

Z_A is condensive when the motor power factor is less than 86.6 per cent, and inductive for greater power factors. Z_B is zero for a motor factor of 50 per cent. For power factors below this value it is a positive resistance. For higher values this impedance becomes a negative resistance. The analysis using this type of connection must be limited to those speed ranges where the power factor is 50 per cent or less. The curves of figure 4 show how these two impedances must vary with the speed if the ideally balanced conditions assumed are to be obtained. In the curves shown in this paper the unprimed values are those calculated for the low-resistance motor, while the primed values are for the high-resistance motor. Considering the speed range between 0 and 50 per cent synchronous speed it may be seen that Z_A is reasonably constant, and that Z_B is quite small actually passing through zero at about 25 per cent speed. This would indicate that for the low-resistance motor Z_A might be assigned an average value and Z_B made equal to zero. For the high resistance motor Z_B' is a negative resistance in this speed range and the connection is not suitable for this motor. Above 50 per cent speed both the low- and high-resistance machines have rapidly changing impedances. No suitable average values are indicated by these curves for the higher speeds.

The type *B* connection is shown in figure 5. The two auxiliary impedances may be determined from the following formulas.

$$Z_1 = -j\frac{E}{I(\cos \theta + 0.577 \sin \theta)}$$

$$Z_2 = j\frac{E}{I(\cos \theta - 0.577 \sin \theta)}$$

Z_1 is a condensive reactance under all conditions. Z_2 is a condensive reactance for power factors less than 50 per cent, and

---

Paper 40-139, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted June 27, 1938; made available for preprinting August 12, 1940.

RAYMOND W. AGER is associate professor of electrical engineering, Cornell University, Ithaca, N. Y.; he was formerly assistant professor of electrical engineering, University of California, Berkeley.

1. For all numbered references, see list at end of paper.

inductive for power factors above this value. For a power factor equal to 50 per cent, Z_2 becomes infinite. For this one condition where the power factor equals 50 per cent the type *B* connection becomes identical to type *A*. Curves showing the variations of these impedances are given in figure 6. Referring to these curves it may be seen that during the starting period, considered as between 0 and 50 per cent speed, the impedance Z_2 changes sign. It is, however, a relatively high impedance throughout this range and may perhaps be omitted. In starting the high-resistance motor about the same capacitive reactance is needed for Z_1' as was required for Z_1 for the low resistance motor. In addition an inductive reactance is needed in position Z_2'. Z_2' varies from 57.7 to 24 ohms in the assumed example. An average value of approximately 40 ohms might be used. Experimental checks on a motor having approximately the characteristics of the high-resistance motor showed that the addition of the inductive reactance Z_2' increased the starting torque. Again no impedances can be chosen which will balance the motors, even approximately, for more than one point in the higher speed range.

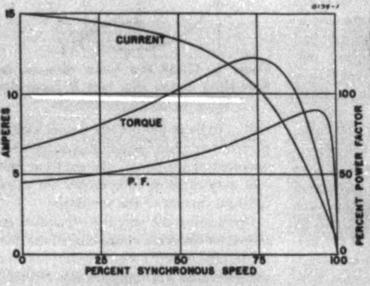

Figure 1 (left). Performance curves for motor with low-resistance rotor

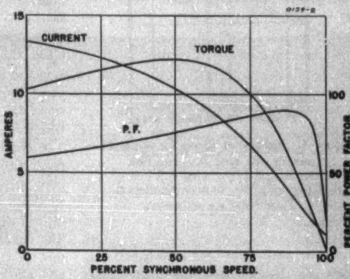

Figure 2 (right). Performance curves for motor with high-resistance rotor

Two-Phase Motors

The type *C* connection for the two-phase motors shown in figure 7 corresponds to the type *A* connection for the three-phase motors. The impedance Z_A is a perfect condenser. Z_B is not a simple impedance. For motor power factors less than 0.707, Z_B is a condensive impedance having a power factor of 0.707. When the motor power factor becomes equal to 0.707 this impedance is reduced to zero, and for higher power factors the impedance becomes an inductance with negative resistance. This type of compensation is of value only where the motor power factor is in the neighborhood of 0.707 as then this second impedance may be omitted. For a high-resistance motor where the starting power factor is 0.60 or higher this impedance may be omitted without too great an error. The values of these impedances are given in the following equations.

$$Z_A = -j\frac{2E \sin\theta}{I}$$

$$Z_B = (j-1)\frac{E(\cos\theta - \sin\theta)}{I}$$

Curves showing the variations of these impedances are given in figure 8. Again no possibility of compensation is indicated by these curves for the higher speeds.

The type *D* connection for two-phase motors corresponds to the type *B* for the three-phase machines. The wiring and vector diagrams of this connection are shown in figure 9. With a condenser used for Z_1, two types of impedance for Z_2 may be used. In the vector diagram the solid lines indicate the values and positions of I_1 and I_2 when a resistance is used for Z_2. The dotted lines show their positions for Z_2 a reactance. In either case I_2 becomes zero for a motor power factor equal to 0.707. The reactance method is the better of the two since where resistances are used negative resistances are required for power factors greater than 0.707. Also for lower power factors the total capacitance required is the same for either method. The impedance curves shown in figure 10 are for the case where Z_2 is a reactive impedance. The equations for Z_1 and Z_2 are as follows. For Z_2 a resistance,

$$Z_1 = -j\frac{E}{I \sin\theta}$$

$$Z_2 = \frac{E}{I(\sin\theta - \cos\theta)}$$

If Z_2 is a reactance these equations become,

$$Z_1 = -j\frac{E}{I \cos\theta}$$

$$Z_2 = j\frac{E}{I(\cos\theta - \sin\theta)}$$

As seen from the curves the low-resistance motor needs two impedances during the starting period. While the ideal impedances vary considerably in the starting range approximate balance may be obtained by choosing average values. Due to the higher power factor of the high-resistance motor the impedance Z_2' is a very high impedance throughout most of the speed range from 0 to 50 per cent speed. This impedance may be left out of the circuit during starting on these high-resistance motors. When the motor power factor is equal to 0.707, Z_2 becomes infinite and the compensation is identical to that of the type *C* connection.

Figure 11 shows still another type of connection in which a two-phase motor

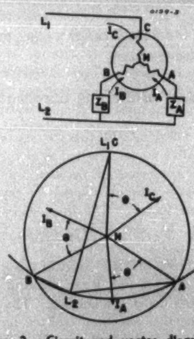

Figure 3. Circuit and vector diagrams for three-phase motors with type A connection

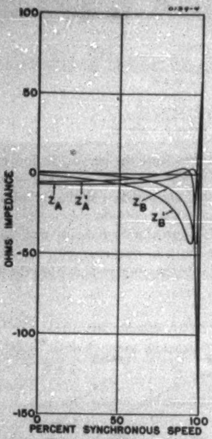

Figure 4. Impedance curves for three-phase motors with type A connection

Z_A and Z_A' are reactive impedances
Z_B and Z_B' are resistances

may be used. This has been called the type *E*. In this case the single-phase voltage is applied to the outside motor terminals and the auxiliary impedances are connected between the neutral point and the lines. Z_1 is a condensive impedance under all conditions. Z_2 is a condensive impedance for power factors less than 0.707 and inductive for greater power factors. At a power factor of 0.707 Z_2 becomes infinite. The variations of these impedances are shown in figure 12. The numerical values are given by the following equations.

$$Z_1 = -j\frac{0.707E}{I(\cos\theta + \sin\theta)}$$

$$Z_2 = j\frac{0.707E}{I(\cos\theta - \sin\theta)}$$

Summary of Starting Impedances

The following table lists average or representative values, selected as giving reasonable compensation between 0 and 50 per cent synchronous speed for the two assumed motors. The impedances calculated for the low-resistance, three-phase motor correspond to a motor power factor of 0.50. Since at this power factor types *A* and *B* are identical they are listed under one heading. The type *C* connection has been omitted for the reasons mentioned above. The values given for the high-resistance motor in the two-phase types have been calculated for a power factor of 0.707 under which one impedance may be omitted. Types *C′* and *D′* being identical have been combined under one heading and type *A′* has been omitted since it would require negative resistance.

In calculating the volt-ampere ratings of the motors the full-load current of the motors originally assumed has been taken as 2.5 amperes.

The second group of values is derived from the first group and takes into account the relative polyphase ratings of the different types of machines. The volt-ampere rating of a three-phase machine is $1.732EI$, while that of a two-phase machine is $2.00EI$. Thus the three-phase machines considered have only had 0.866 the rating of the two-phase machines in types *C* and *D*. The type *E* two-phase motors have phase voltages 0.707 times those of types *C* and *D* and are therefore smaller machines in that ratio. The condenser volt-ampere and microfarad ratings in this part of the table have been increased so that they correspond to those of machines having the same ratings as the two-phase types *C* and *D*. The values of relative weight of the motors are included to point out an advantage which the three-phase motors have over the two-phase motors due to the higher distribution factors of their stator windings.

Since some motors use condensers during the starting period only, the tabulation of per cent of the winding used and the volt-ampere rating of the motor when operated single-phase without auxiliary impedances is included. For motors so operated these values will serve to show the advantages which the three-phase and the two-phase type *E* have over the normal method of connection. The advantages indicated here become of especial importance for motors having a high ratio of exciting current to rated full-load current. In those motors where only a small part of the stator winding is used when operated single-phase, the exciting current may equal or even exceed the rated full-load current of the winding.

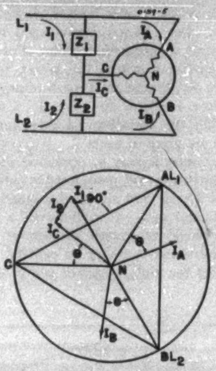

Figure 5. Circuit and vector diagrams for three-phase motors with type B connection

Considering the starting capacitors required for the proper balancing of the low-resistance motors it will be noted that the smallest total volt-amperes are required by the three-phase motor. Also the three-phase motor requires only one capacitor while the total capacitance must be split in the case of the two-phase designs. Although the volt-ampere capacitance is less for the three-phase motor the number of microfarads required is higher than the type *D* since the larger part of those used in the latter connection are operated at a higher voltage. Transformers are sometimes used to get higher condenser voltages. Where these are used the main consideration is the volt-ampere rating of the capacitor.

For motors having higher starting power factors there seems to be little

Table I

	Low-Resistance Motor			High-Resistance Motor		
	A and B	D	E	B′	C′ and D′	E′
Z_A or Z_1 ohms	$-j6.90$	$-j14.0$	$-j3.60$	$-j7.30$	$-j12.35$	$-j4.36$
Z_B or Z_2 ohms	None	$-j20.0$	$-j12.5$	$+j40$	None	None
Z_A or Z_1 microfarads	384	189	736	363	215	608
Z_B or Z_2 microfarads	0	132	212	Inductive	0	0
Total microfarads	384	321	948	363	215	608
Condenser volt-amperes	1,450	1,930	1,790	1,370	1,620	1,146
The following values have been corrected to take account of the relative polyphase ratings of the motors:						
Condenser volt-amperes	1,670	1,930	2,530	1,580	1,620	1,620
Condenser microfarads	443	321	1,340	418	215	860
Condenser voltage	100	141 and 100	70.7	100	141	70.7
Relative weight of motor	95	100	100	95	100	100
If the machines are operated single-phase without auxiliary impedances for full speed running the following factors should be noted:						
Per cent of winding used	67	50	100	67	50	100
Volt-ampere motor rating	289	250	354	289	250	354

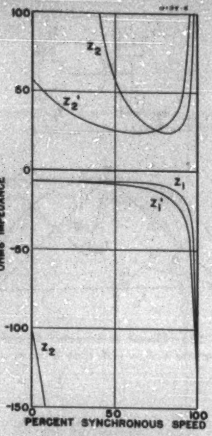

Figure 6. Impedance curves for three-phase motors with type B connection

All impedances are reactive

choice between the different types of connection on the basis of condenser kilovolt-amperes required. The three-phase motor, however, requires a reactance coil as a second impedance which the two-phase designs do not require. In comparing the types D' and E' it should be pointed out that the condenser kilovolt-amperes required is the same in each case and the main difference is the voltage applied to the condenser. Since the voltage across the condenser in the type E' connection is one-half that used in the type D' the capacitance used must be four times as great. If a one-to-two transformer were used with the type E', doubling the condenser voltage, the starting condensers used in the two types would be identical except for modifications needed to make allowances for the transformer exciting current and losses. The main question which arises then is as to the relative advantage of the omission of the transformer versus the use of the entire winding for running.

Unsymmetrical Motors

A disadvantage possessed by unsymmetrical machines is that coils of different wire sizes and number of turns are needed. While not a major item it would be advantageous to use the same sized windings throughout. Three-phase machines with unsymmetrical windings cannot have balanced flux conditions except under special circumstances. Because of this and because they are not used by the industry they have not been considered. Two-phase unsymmetrical machines may readily have balanced flux conditions and are extensively used by industry.

Balanced flux conditions, as used above, are obtained when each phase of the stator supplies the same power and magnetizing force to the rotor, and these are supplied at times corresponding to the mechanical displacement of the phases. In a symmetrical two-phase machine this condition exists when the currents in the two phases are equal and displaced 90 degrees in time. Where the two phases have different voltage ratings, the currents must be different in inverse ratio so that the power and kilovolt-amperes remain the same. The currents in the two phases must still be displaced 90 degrees in time if the coils are displaced 90 electrical degrees on the motor frame.

In figure 13 is shown the vector diagram of the usual type of connection which corresponds to the type D except that phase A is not wound for rated line voltage. In the condenser motor this starting winding is usually wound for a higher voltage than the line voltage. By changing the voltage for which this phase is wound three main effects are produced. First the voltages across the impedances are changed, second the current requirement in that phase is changed, and, third the phase of the voltage across Z_1 is changed. As results of these changes we may find changes in the following: the kilovolt-amperes of the condensers required, the size of the condensers, the arrangement of these condensers, and the power factor at which compensation may be accomplished using a single impedance Z_1. A single condenser in position Z_1 will give perfect compensation when $\phi=\theta$, where tangent ϕ is the starting winding voltage to the running winding voltage. The kilovolt-amperes in the main condenser Z_1 is a minimum for the ratio tangent $\phi=1$, and increases as we depart either way from this value. When ϕ is smaller than θ, Z_2 is also a condenser. Including Z_2 the minimum total kilovolt-amperes of condenser capacity required occurs when $\phi=\theta$. The capacitances of both condensers decrease as the starting winding voltage is increased. The optimum voltage ratio to use would seem to be the highest value possible without overstressing the condensers. For values of ϕ greater than θ, the impedance Z_2 becomes inductive.

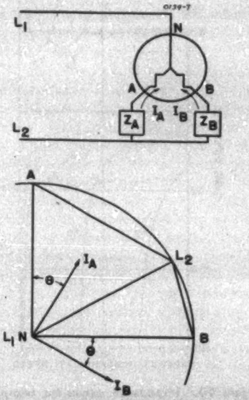

Figure 7. Circuit and vector diagrams for two-phase motors with type C connection

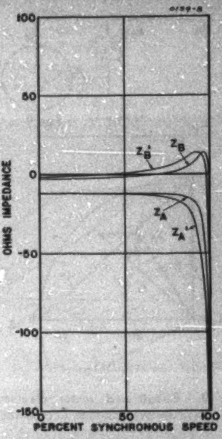

Figure 8. Impedance curves for two-phase motors with type C connection

Z_A and Z_A' are reactive impedances
Z_B and Z_B' values are to be multiplied by $(j-1)$

The two-phase type D with unsymmetrical windings may be compared with the type B. If the two-phase machine were wound with a ratio tangent $\phi=1.732$ and were compensated for a power factor of 0.50, only one impedance Z_1 would be needed. Compensating the three-phase motor for this power factor also would require only one impedance. Correcting for the relative polyphase motor ratings the following comparisons may be made. The condenser voltage for

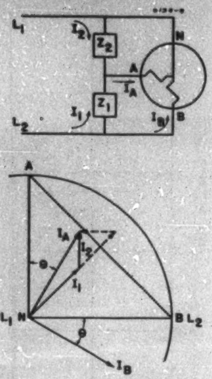

Figure 9. Circuit and vector diagrams for two-phase motors with type D connection

the two-phase motor would be twice that for the three-phase motor. The condenser capacitance for the two-phase motor would be one-fourth that for the three-phase motor. The condenser kilovolt-amperes would be the same for either motor.

The following formulas apply to the unbalanced two-phase type *D* connection.

$$Z_1=-j\frac{E\sin\phi}{I\cos\phi\cos\theta}$$

$$E_1I_1=\frac{EI\cos\theta}{\sin\phi\cos\phi}$$

$$Z_2=-j\frac{E\sin^2\phi}{I\cos\phi\sin(\theta-\phi)}$$

$$E_2I_2=\frac{EI\sin(\theta-\phi)}{\cos\phi}$$

In these equations I is the phase B current.

Figure 14 shows the vector diagram for the unsymmetrical type *E* connection. This modification of the type *E* connection corresponds to a motor in which the two phases have been wound for different voltages, or to one in which the stator has been uniformly wound but the neutral is not exactly the midpoint of the winding.

A single condenser may be used for balancing this type when $\cos\theta=\sin\phi$. As the voltage ratio of the two windings is changed the capacitance required for compensation is also changed. The minimum total capacitance is required for the symmetrical condition where the two phases are identical. This condition does not result in the minimum total kilovolt-amperes which occurs for smaller values of ϕ. When ϕ is less than (90 degrees $-\theta$), Z_2 is inductive. It is questionable if operation in this region is desirable so that minimum kilovolt-ampere condenser rating would, for practical purposes, occur where $\cos\theta=\sin\phi$. For single-phase running without auxiliary impedances the current rating of the higher voltage phase would have to be used in determining the volt-ampere rating of the motor.

The equations covering the unsymmetrical type *E* connection are given below.

$$Z_1=-j\frac{E\sin^2\phi\cos\phi}{I\sin(\phi+\theta)}$$

$$E_1I_1=\frac{EI\sin(\phi+\theta)}{\cos\phi}$$

$$Z_2=+j\frac{E\sin\phi\cos^2\phi}{I\cos(\phi+\theta)}$$

$$E_2I_2=\frac{EI\cos(\phi+\theta)}{\sin\phi}$$

Where $I=I_A\cos\phi=I_B\sin\phi$, and E is the voltage of the single-phase line. Since I_A and I_B both change as ϕ changes a general value of I was desired in the above equations. This particular value was chosen since line voltage times this current was equal to the volt-amperes of either phase.

Conclusions

The results of this analysis show that no appropriate values of impedance can be found for the full-speed running conditions which will give polyphase performance for more than a single point. This statement applies equally well to all the connections considered. It does not mean that the use of condensers in the running circuit cannot be justified. Considerable benefit may be derived from the use of condensers, but these condensers do not make the single-phase performance of the motor equivalent to the polyphase throughout the range of normal operation. A single condenser of proper size may be used to balance the motor for some definite load. This load corresponds to a motor power factor of 0.50 for the three-phase connections and of 0.707 for the symmetrical two-phase connections. For the unsymmetrical two-phase connections the power factor of compensation will depend upon the voltage ratio of the two phases. The ability to balance certain motors at the higher power factors, or higher loads, may be an advantage in some cases.

The best connection to use depends upon the relative weights given the factors involved. For low-resistance motors having starting power factors in the neighborhood of 0.50 the three-phase and the unsymmetrical two-phase type *D* connections require the lowest kilovolt-amperes of condenser capacitance during the starting period, and all this may be in one unit. These two-phase machines should have a voltage ratio of the starting to running winding of about 1.7 to 1. Where the motors have higher resistance, resulting in starting power factors of perhaps 0.60 and above, the symmetrical two-phase types or the unsymmetrical type *D* having a voltage ratio of about 1.25 to 1 are indicated as requiring the

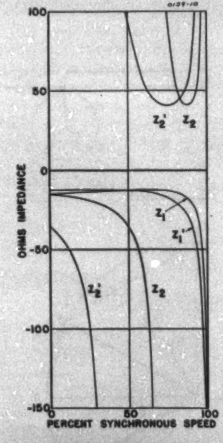

Figure 10. Impedance curves for two-phase motors with type D connection

All impedances are reactive

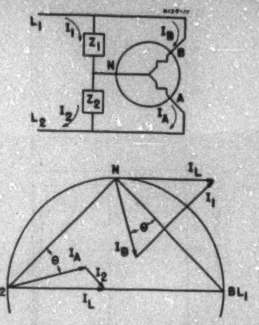

Figure 11. Circuit and vector diagrams for two-phase motors with type E connection

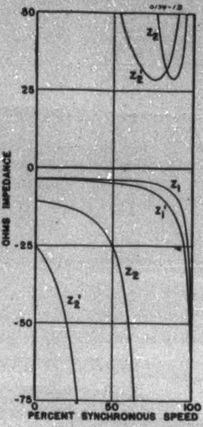

Figure 12. Impedance curves for two-phase motors with type E connection

All impedances are reactive

minimum kilovolt-amperes of capacitance. Where the deciding factor is the capacity of the condenser the connections which place the highest voltages on the condensers must be used, and the unsymmetrical type *D* is the obvious choice unless boosting transformers are to be used. If the deciding factor were the full-speed volt-ampere rating of the motor then the two-phase type *E* would be indicated.

The kilovolt-amperes of condenser capacitance required at starting by the high-resistance motors is not greatly different from that required by the low-resistance motors, the connection requiring minimum kilovolt-amperes being assumed used in each case. This is true in spite of the reduction in starting current caused by the increased rotor resistance. Thus increasing the rotor resistance will have little effect upon the condenser kilovolt-amperes required for complete balancing. The starting torques of these higher resistance motors are higher, so that the starting torque per kilovolt-ampere of condenser will be higher in these motors.

While a small matter in most instances, simplicity in connections for reversing service might be desired. When a single impedance can be used in the three-phase type *B* and the symmetrical type *E* the only change necessary for reversing is the changing of the line side of the condenser from one line to the other.

In speculating upon the indications which this analysis has yielded it has seemed that an excellent motor would be one having a high-power factor and low current at starting. This current and power factor should remain relatively constant during the starting period. For full-speed running the resistance of the rotor circuit should be low and a large part of the stator winding should be active even though running condensers were not used. This combination may be best approximated by a properly designed double-squirrel cage machine. Where the motors are too small to make the double-cage construction economical, deep narrow slots should be of benefit. With the high-starting power factor the type *E* connection could be used with a single impedance at starting. The type *E* connection would also permit the use of the entire stator winding in normal running. The deeply imbedded rotor winding would supply the low-resistance circuit for carrying the main field into the quadrature position. The use of a boosting transformer on the condenser would probably be desired if the motor were wound for low voltage.

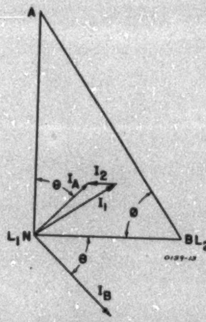

Figure 13. Vector diagram for the unsymmetrical type D connection

This paper has been prepared with the thought in mind that complete balance of the motors was desired. Many applications would not require the high torques which this work has supposed to be needed. Reduced capacitance in the starting circuit will result in reduced starting torque, and this reduction in the capacitance may be demanded by the economics of the case. An item effecting the balance which it is possible to obtain is the saturation of the iron parts of the magnetic circuit. With the higher saturations found in some machines the inductances of the windings are not constant, and the magnitudes and the phase angles assumed for the currents in this work may not be attainable. If this is the case some modifications of the calculated impedances may be desired.

Design Factors Involved in the Design of Domestic Motored Appliances

L. C. PACKER
ASSOCIATE AIEE

Synopsis: In all domestic motored appliances, there are certain general design factors to which more detailed design factors are related, depending upon the appliance involved. In this paper the various design factors are enumerated and explained in a way which it is hoped will be of assistance to the many thousands of engineers engaged in the design of motored appliances. Curves show typical speed-torque characteristics of motors used to drive various types of appliances. Tables show the types of motors used with different types of appliances and the principal factors causing noise. General design factors involved in motored appliances are discussed as a group.

Introduction

THE designer of domestic motored appliances is today accepting as his limitations the real values of function, utility, and cost. With these basic elements to start with, motored appliances are now approaching and in many instances, have surpassed all expectations of those who felt the need of a product that functioned both in the home and salesroom.

The consumer is the judge at all times. When he purchases a product and uses it in his home, there must evolve out of this ownership a feeling of satisfaction as to the usefulness of the product. He has every right to expect the utmost in the product. Domestic motored appliances of today are noteworthy examples of what can be done when every consideration has been given to the demands of the consumer. These appliances have higher efficiencies, better quality and appearance. They are more compact, more quiet, and lower in cost.

It is the designer's duty to analyze the factors involved in domestic motored appliances and from this analysis produce the finished product. The author attempts to show in this paper the design factors involved and their application to domestic motored appliances. However, the electrical equipment will be given greater prominence because it is common to all motored appliances, whereas a design treatise on each type of motored appliance would require an individual paper.

Domestic motored appliances cover a wide range of uses, types, and sizes. There are various classifications, such as large and small (or counter) appliances, portable and stationary, or plug-in and permanently wired appliances. However, the author is classifying them according to their use in the various parts of the home as this is often the classification used for marketing purposes.

Kitchen

Refrigerator
Food preparing machines
Dishwasher
Garbage disposal machines

Laundry

Washing machines
Ironing machines

Floor cleaning and finishing

Vacuum cleaners
Floor polishers

Heating

Oil burners
Coal stokers
Unit heaters
Portable room heaters

Air conditioning

Air-conditioning units
Fans
Humidifiers

Bathroom

Hair dryers

Sewing room

Sewing machines

Lawns and garden

Lawn mower
Hedge trimmer

Entertainment

Phonographs
Motion picture projectors

Home work shop and garage

Portable electric drills
Portable electric saws
Small drill presses
Small lathes
Small grinders
Small polishing equipment

Farm house and rural dwellings

Pumps
Churns
Feed cutters

Before starting on a particular design it is necessary for the designers to become familiar with the following subjects and keep them in mind during the design stages.

1. Public demand.
2. Price at which it must be sold.
3. Manufacturing facilities.
4. Marketing.

The following general factors must then be analyzed by the design engineers, and a complete study made of each one.

A. The use for which the appliance is intended.

B. Operation.

C. Frequency and length of time used.

D. Abuses to which appliance is subjected.

E. Quietness.

A. *Use*. The use for which an appliance is intended is the important thing, and requires a thorough study of it. Efforts should be directed toward designing the appliance for a particular use only and not try to make it a jack-of-all-trades. If a design tries to cover too broad a field it soon loses its identity and the efficiency and utility are lost to the use for which it was originally intended.

B. *Operation*. The principles of every phase of operation and the load should be firmly established by thorough study and research before an appliance is ready for the final design stages. Further studies and tests of samples of the final design should then be made under actual operating conditions to determine whether or not changes are necessary prior to the production of the final product.

C. *Frequency and length of time used*. This establishes the temperature rating and very often the type of motor, structural details, and materials to be used.

Some appliances may operate for only a few minutes a day, whereas others may operate for a total of six or eight hours every day of the week. Assume, for instance, a total of 5,000 hours' life for an appliance. A vacuum cleaner is used for an average of about one hour per week. Five thousand hours of operation would represent about 50 years in service. Some machines are so built that they would give that service if given proper attention by the user.

Paper 40-154, recommended by the AIEE committee on domestic and commercial applications, and presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. Manuscript submitted August 12, 1940; made available for preprinting September 5, 1940.

L. C. PACKER is design engineer in the merchandising engineering department of the Westinghouse Electric and Manufacturing Company, Springfield, Mass.

[1] For all numbered references, see list at end of paper.

For refrigerators and air-conditioning units, for instance, 5,000 hours of operation represents about two years or less service life.

The heating season, in New England and in some other sections, is from October to late in April or May. In many cases the burner may run throughout the summer for heating water. The running time of the burner may be 2,000 hours for the season. On the basis of 5,000 hours' life, the burner would have a service life of only about $2^{1}/_{2}$ years.

The service life for which an appliance is to be designed has never been definitely established because of the many factors involved. The initial investment in a given appliance may mean a great deal of money to some people; therefore, it is necessary that they keep the appliance in service as long as possible. They are willing to forego the advantages that may be obtained in later models. To other people the initial cost does not represent a large investment. They are more anxious in many cases to replace their appliance more frequently to gain the advantages of later models. Therefore, the designer must choose the design and materials that will satisfy the application and give a sufficiently long service life to justify the initial cost to the consumer. The average consumer may then be better able to replace the old model with a new one having the many advantages gained by aggressive research and constant improvements in design and manufacturing methods.

D. Abuses. The abuses to which an appliance may be subjected should be analyzed, as often the success of the appliance is jeopardized because not enough thought was given to them. Considerable impetus has been given to the market for motored appliances by the gradual standardization of voltages and frequencies. However, considerable abuses are experienced by trying to use an appliance on voltages or frequencies, or both, outside the limits for which it was designed. This results in overheating on overvoltage or low frequencies and decrease in torque on low voltages.

Overloading an appliance beyond its capacity is a common fault. Therefore, proper protection should be provided. Failure to lubricate an appliance that requires replenishing the lubrication periodically is another source of trouble. To prevent this trouble a lubrication system should be provided that does not require any additional lubricant or one in which it is a simple matter to add more lubricant. However, the addition of too much oil or grease will be another source of trouble. For instance, in a food mixer excess oil will get into the food. In a sewing machine, the excess oil will get onto the cloth. There are many similar cases that could be mentioned.

Often the bag and rotary brush of a vacuum cleaner are not cleaned frequently enough and this results in lowering the efficiency of the machine. Neglect in defrosting a refrigerator or overloading it reduces its efficiency considerably.

Improper care of the appliance should be anticipated and corrective measures taken in the design to eliminate as many abuses as possible and put out intelligent instructions where the abuses cannot be met by design. There are also many abuses due to handling in service and in transportation which may be anticipated and at least partial protection provided.

E. Quietness. It would be desirable if all motored appliances were noiseless, but that is impossible with rotating apparatus. It is possible, however, to reduce the noise to a degree where it is acceptable to the average user. There are limitations depending upon the type of the apparatus, speeds, use, location of the use, mechanical and electrical limitations, and cost.

The housewife has learned to expect a vacuum cleaner, food mixer, or sewing machine to be noisy, but since she uses it infrequently she will endure a certain amount of noise although she would naturally prefer it to be quiet. However, any great amount of noise in a refrigerator, fan, air-conditioning unit, or oil burner will be annoying because it is running for a portion of the day every day of the year or season. Some of the noise is carried through the walls and floors to other parts of the house, or apartment. Infrequent noises or continuous noises produced by bumping, rattles, or other foreign noise causes apprehension in the mind of the user as to whether or not the appliance is operating properly.

There are high-frequency noises in the motor which may be more annoying to some people than to others. The 120-cycle noise for a 60-cycle motor cannot be eliminated but its intensity can be reduced. Many of the higher frequency noises caused by harmonics can be eliminated through proper design of the motor.

The noises prevalent in an appliance can be divided into four divisions:

1. Motor.
2. Intermediate drive, if any.
3. Functional parts.
4. Resonance in complete unit.

1. Most portable motored appliances are driven by high-speed Universal type a-c-d-c motors in order to reduce the weight of the motor. They are inherently noisy because of the high speed of the motor and driven elements that make up the appliance.

The appliances using constant speed motors do not operate at speeds above 3,600 rpm; in fact, most of them operate at about 1,700 rpm. Therefore, the noise due to the speed is less. There may be other noises, however, that may be just as annoying if one must listen to them all day.

2. The driving unit between the motor and the device, such as gear reductions, couplings, and belts, may be a source of a large per cent of the total noise if not properly designed and manufactured.

3. The noise of the functional parts of the appliance, such as fan blades, pumps, and mechanisms, form a part of the total noise. Any one of the three main sources of noise mentioned above may be responsible for the predominating and most annoying noise.

4. In some cases it has been found that the predominating noise was not due to any one of the above units independently, but the unit was operated at a speed where some frequency component was close to the natural period of some part or parts of the complete unit.

Principal Design Factors

The principal design factors that determine and make up the design of the electrical equipment for motored appliances will be explained in general. It might be well to mention here that the motored appliance design engineer must of necessity be well versed in human engineering, manufacturing, and costs, in addition to engineering fundamentals, as he is placed in contact with people in all walks of life in order to gather information and experience. Engineers will no doubt agree that the engineer who gathers the most valuable information so necessary in design work, gains it by tact and diplomacy whether he is dealing with an editor of a woman's magazine, housewives, the workman at the bench or machine, or cost clerk. The engineer must always keep in mind that only through the combined efforts of the many people with whom he comes in contact and his ability to accept constructive criticism will a design be successful.

Motor

The application determines the horsepower, temperature rating, speed, type, and size of motor. Fractional horsepower motors are used in most applications with few exceptions. They are produced by mass production at minimum costs, and include standardized ratings, sizes, and types so as to assure the manufacturer of motored appliances, etc., the proper motor at low prices.

It is therefore wise to first survey the standardized motors and if possible use them to get the benefit of low costs. If using them sacrifices some mechanical feature a slight modification of a stand-

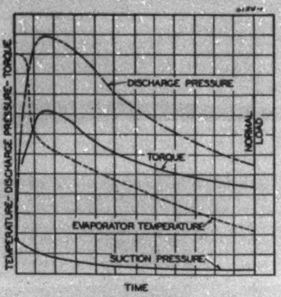

Figure 1. Typical load cycle of a refrigerator at pull down

ard motor may solve the problem. If the use of either of the above motors means a sacrifice in the design of the appliance from a functional or appearance standpoint, then a "custom built" or "built in" motor may meet the requirements.

Rating—Performance

The normal load at which the motor will operate for the greatest length of the time generally establishes the horsepower, speed, and temperature rating.

The speed depends upon the type of load and appliance. For instance, all portable appliances such as food mixers, vacuum cleaners, etc., must be light in weight. The Universal a-c-d-c motor is very desirable for these appliances because the horsepower per pound weight is very high, depending upon the speed.

Other appliances use motor speeds from approximately 870 to 3,450 rpm.

The motor must have sufficient torque to start the load from rest and take it up to speed. It must also have sufficient pull-out torque to prevent the motor from stalling due to a reasonable overload at minimum voltage conditions.

The efficiency should be as high as possible. The limiting factors are the type of motor, first cost, and economy of operation.

The starting current must not exceed the maximum values established by NEMA, National Electric Code, and power companies.

The voltage and frequency range over which the motor must operate has considerable bearing upon the design. For domestic service the voltage will range to a great extent from 115 to 120 with about five per cent of the total house voltages below 115 and above 120. This also includes odd frequencies from direct current through 50 cycles. In countries outside the United States, voltages may be encountered ranging from 90 to 250 in combination with frequencies ranging from direct current to 60 cycles.

The designer should not try to cover too wide a range of voltages and frequencies as it may lead to making sacrifices in the appliance and increase the cost. He should also keep in mind that the torque of the motor decreases with a decrease in voltage from that for which the motor is designed and the temperature of the motor winding will be increased with an increase in voltage.

The following examples of performance are given to illustrate the duty cycle of a few appliances such as refrigerators and air-conditioning units, washing machines, and vacuum cleaners. More detailed explanations are given for refrigerators and air-conditioning units than the others because there is less generally known about them.

Refrigerator and Air-Conditioning Unit Performance

In general the two types of appliances are similar in performance and in some cases the compressor units are similar. Although the method of loading is different, the same type of "pull down" load cycle applies to both units but to a different degree as the temperature gradient for an air-conditioning unit will be less than for a refrigerator.

There are different types of compressors. In most domestic refrigerators a single-phase motor is built into and hermetically sealed with the compressor. In some cases this method of construction also applies to air-conditioning units. For this type, a relay is mounted outside of the compressor unit to drop out or pick up the starting winding as required. There are various types of relays used for this purpose, classified as either thermal or magnetic types. There are variations also in each type, all of which perform their duty in an acceptable manner. For the performance explained below, the magnetic type is assumed. The coil of the relay is in series with the main phase or running winding and the contacts are in series with the starting winding.

Since the type of "pull down" load cycle is the same for both types of units, the refrigerator performance is assumed here. Assume a refrigerator taken out of stock and set up in a warm kitchen. The evaporator of the unit is at the same temperature as the kitchen. The box is filled with food and the door is closed. The circuit is closed and the motor starts the compressor. Figure 1 shows the performance of the unit from where it starts at a stabilized condition and passes through a load cycle until the evaporator reaches a predetermined temperature. At the instant of starting the suction and discharge pressures are the same.

It is to be noted in this case that the load reaches a maximum in about eight per cent of the time that it takes to reach the normal load point and is at the point of greatest differential between the suction and discharge pressures. The average running load may be considered the normal load. However if the box is overloaded the suction pressure will increase, thus increasing the load.

Figure 2 shows the performance of the motor from start throughout the "pull down" cycle. Starting at point *A* the motor pulls up to point *B* on the curve, at which time the relay opens the contacts and drops out the starting winding. The motor then continues from point *C* to run on the main winding. On the "pull down" the speed increases from *C* up to *D*, then back to *E* at maximum load. The load then decreases from there to normal load causing the motor speed to increase from *E* to normal load point *F*. If the load at any time increases too much during its operation, the speed may drop down to point *C*, where the relay closes the contacts, cuts in the starting winding at *B* and tries to get up to speed again. If the motor goes through several of these cycles the motor winding may heat excessively and cause the winding protective device to break the circuit. Possibly by the time the protective device closes again the compressor has equalized or if an unloader is used, the motor will take the compressor up to speed. Often the load may be at a point around *D* or any other load considered as an overload, for a sufficient time for the protective device to break the circuit to protect the

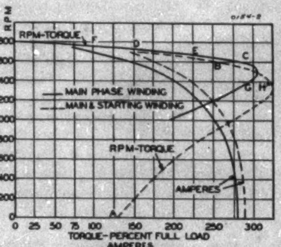

Figure 2. Speed-torque-ampere characteristics of a split-phase-start single-phase induction run motor for refrigerator

winding. Overloading the box, increased ambient temperature or both, will cause an overload on the motor and increase its running time.

The normal horsepower rating will be at the normal load established by the temperature that the evaporator in the cabinet is to maintain, and is an average load. For instance, the control may be so set that when the compressor is running it will bring the evaporator temperature below normal before it cuts out. The temperature will slowly increase until it may be an equal amount above normal at which time the control closes the circuit and the compressor starts. The compressor will continue to cycle over this range or possibly a greater range, depending upon the load or room temperature. The motor should have its maximum efficiency at normal load conditions and if possible over a range near normal load.

Because there are overload conditions that must be considered, it is necessary that the winding does not exceed a safe temperature, for the type of insulation used, over the period of time that the unit may be called upon to operate within the range of normal overloads and extreme cases of operating at normal loads.

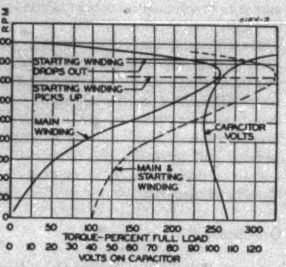

Figure 3. Speed-torque characteristics of a capacitor-start single-phase induction run motor for a refrigerator or air-conditioning unit

Washing-Machine Performance

In a washing machine the tub is filled to the proper level with hot water, soap is added and then the clothes are put in. The motor is then started. The time of operation may be from 10 to 30 minutes depending upon the weight of clothes. The dirty water is removed. Sometimes a pump is attached which is operated by the same motor to pump the water to a drain. Cold water is put into the tub for rinsing the clothes. This water is drained off and clean water added to the tub. Bluing is added to the water and the clothes rinsed or left standing in it for a while and then rinsed. Then the clothes are put through the wringer or spinner, driven by the washing machine motor, to remove the excess water. This operation may take 10 or 15 minutes.

This application has an intermittent load cycle of short duration. It has overloads but for short periods, such as trying to put too many clothes in, or putting too much through the wringer. However, experience has shown that a "short time" rating is satisfactory.

Vacuum-Cleaner Performance

Vacuum cleaners operate over a range of load and with appreciable speed variation. Take, for instance, a motor-driven brush type vacuum cleaner. The brush will take a small part of the total load but the air drawn through the nozzle and fan case will require most of the output of the motor. If the height of the brush is not properly adjusted the load will increase somewhat, but the greatest variation in load is caused by the height of the nozzle above the floor, and whether the cleaner is moving over a bare floor or on different kinds and thicknesses of rugs. The total cleaning time may be less than 30 minutes for any day. Therefore, the motor does not run long enough to get up to maximum temperature. A short-time or intermittent rating should be satisfactory but from a fire hazard standpoint, the Underwriters' Laboratories feel that continuous operation should be expected with the dust bag in place, until the temperature becomes constant with an average load. There are no protective devices on vacuum cleaners; therefore, if the housewife should leave the motor running the above condition would be obtained. It usually takes approximately one hour for the temperature to become constant.

Temperatures are discussed in these examples to illustrate the importance of the proper rating and maximum temperatures on specific appliances. Temperatures are discussed more generally under that subject.

Temperature

The temperature rating is normally set at the normal load and based on the maximum operating time. The motor should also withstand temperatures due to reasonable overloads encountered in the operation of the appliance and at the maximum voltage of the guaranteed voltage range and frequency range. While it may be desirable from a selling and stock standpoint it may be that it is not economical from a cost standpoint.

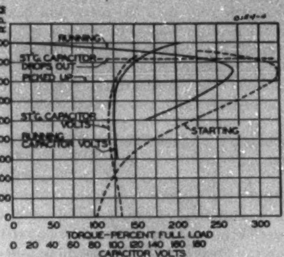

Figure 4. Speed-torque characteristics of a capacitor-start-and-run motor for a refrigerator or air-conditioning unit

There are various limiting hot-spot temperatures established for various classes of insulations by AIEE. Therefore, it is possible to set a rating based on operating time and load. It may be for continuous, short-time or intermittent service. Ambient temperatures to be encountered have considerable bearing upon the temperature rise. The method of measuring temperatures such as by thermometer, resistance and/or thermocouple must be considered in establishing the rating. Proper consideration of these factors often results in considerable reduction in the cost of the motor and appliance, although a smaller motor may be more noisy magnetically.

Consideration must be given to the effect of temperature upon the mechanical parts of the motor, control and appliance. Where there is a combination of copper and steel parts the copper should have only two-thirds the temperature of the steel parts to have the linear expansion of the two metals equal, because the linear expansion of steel is only two-thirds that of copper. In commutator type motors, neglect in considering temperature may result in uneven expansions and warping of the commutator, and breaking of leads to the commutator, high bars and poor commutation.

Clearances between the shaft and sleeve bearings may be affected so as to cause loss of oil film, excess friction or binding. The clearances in ball bearings may be reduced and cause excess friction and noise, and even binding. End play may be reduced to a dangerous point. Temperatures should be considered relative to the stator, rotor, shaft fits and balance. The stator may become distorted at the teeth, and expansion of the rotor diameter may cause the air gap to be reduced so that it causes an unbalanced magnetic pull upon the rotor, and bend the shaft, thus causing the rotor to rub or cause a slip-frequency noise. The rotor may even drag on the stator and further increase the temperature, reduce the torque at the shaft and increase the watts. Reduction of the air gap may also increase the magnetic noise and affect the torque.

High temperatures may also cause excess friction between cylinders and pistons of compressors, also in gears of various appliances causing excess friction and noise. Press fits of parts should be suitable where high temperatures are involved as standard press fits will probably not be sufficient.

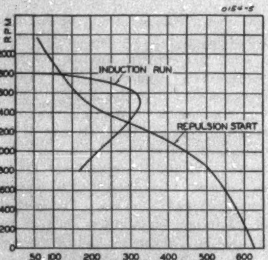

Figure 5. Speed-torque characteristics of a repulsion-start induction-run motor for a refrigerator or air-conditioning unit

Type of Motor

The type of motor to be used depends upon the characteristics required. It is advantageous to use standard motors where possible. For instance, standard $^1/_6$- or $^1/_4$-horsepower, 60-cycle, 1,725-rpm split phase start induction run single-phase high torque short-hour motors are made in large quantities by many motor manufacturers for washing machine drive, and offer many advantages in cost, delivery and service. However, it should be kept in mind that these motors are designed for a specific purpose where there is infrequent starting and a limited time of operation. One of the most serious problems in the application of split-phase high-torque motors is the starting current, which may not in some cases meet the requirements of the power companies. However, due to the infrequent number of starts in washing machine service, they are generally accepted. Other disadvantages of these motors for general application are the greater tendency toward noise and lower efficiency and power factor.

Fractional-horsepower motors are also made in standard ratings and types, open, semienclosed, enclosed, solid or resilient mounting, sleeve bearing and ball bearing; therefore, the appliance manufacturer has a large and varied field from which to choose a satisfactory motor.

Very often "custom built" or "built in" motors are required. The user will gain much if he will use as many of the motor manufacturer's standard parts as possible as new tools are expensive and special parts made in small quantities outside the mass production lines cost more than standardized parts.

The curves showing the different motor characteristics represent motors for specific applications and starting torques, pull-in or pull-out torques are out of line in some cases with standardized NEMA ratings.

For applications requiring high starting and pull-in torques at low starting current, the capacitor-start single-phase induction run motor may be used. Electrolytic capacitors are usually used because the operating time is short and cost of them is low. It is desirable to keep the voltage across the capacitor as low as possible. This type of motor also has fairly high efficiency. Figure 3 shows the characteristics of a capacitor-start motor for a compressor of same size and type as figure 2.

Figure 4 shows the characteristics of a capacitor-start-and-run motor for same application as figure 2. This type of motor is used where higher efficiencies and power factors are desirable.

Figure 5 is a repulsion-start induction-run motor. This type is desirable where unusually high starting torques for a given current are required.

Figure 6 shows a shade-pole type, commonly used for driving fans or other applications requiring low starting and pull-out torques and low starting current.

Figure 7 shows the characteristics of a Universal-type motor used on high-speed applications where weight is a factor.

Insulation

The insulation in most motors for appliances is of the class *A* type. Special insulation is used in hermetically sealed refrigerator and air-conditioning compressor motors. The life of the motor depends upon several factors, one of which is the insulation. The insulation life is also dependent upon several factors, such as temperature, expansion and contraction during load and off periods, electrical stresses, vibration, mechanical stresses, exposure to air subjecting it to oxidation, and moisture.

To withstand the various strains and deterioration due to load and temperature a thorough study must be given to the possible effect of each factor and safeguard against harm to the insulation. Proper impregnation treatments of the winding will minimize the deterioration due to oxidation caused by exposure to the air and moisture.

Quietness

In order to eliminate noise or to reduce it, an analysis must be made as to the

cause of the noise. Table II shows from experience the principal sources of noise for the various types of appliances. The application of a noise analyzer will show the frequency and amplitude of the noise of each component part. By examining table II showing the principal sources of noise in various appliances it is noticed that the motor and unbalance are common to all types of motored appliances. This does not mean that they are responsible for all of the noise. In the case of vacuum cleaners, if the motor noise was entirely eliminated the total noise would not be reduced very much. First analyze the noises produced by the motor and unbalanced conditions in a vacuum cleaner and other appliances.

The Universal concentrated pole-type a-c-d-c motor is used for many portable appliances such as vacuum cleaners, food mixers, sewing machines, and portable tools. The speeds vary from 3,000 rpm for sewing machine motors, approximately 10,000 rpm for vacuum cleaners and food mixers, up to about 20,000 rpm for portable tools. The rotational frequencies cause a great deal of the noise. This noise can be kept to a minimum by the choice of the proper number of slots in the armature, and design of the pole face. The surface speed of the commutator is often as high as 3,000 feet per minute. For the best commutation and brush life the commutator mica bars should be as thin as practical and should be undercut. With the commutator running at this speed with undercut mica slots under the brushes it is absolutely necessary that the commutator surface be machined as nearly true as possible with respect to the bearings; otherwise, while some noise will still be present, a poor or untrue surface will result in excessive noise as well as poor commutation.

The grade of material in the motor brushes also reflects upon the noise; therefore, the choice of brushes is important. The clearance around the brushes in the brush holder is important and should be such that chattering of the brushes will not result, but not too close as the brushes may not move freely.

These high-speed armatures should be dynamically balanced to keep noise to a minimum, which increases the life of the bearings.

The noise in single-phase motors may be attributed to several factors all of which must be anticipated and corrected. Inferior shaft and sleeve bearing surfaces, excessive clearances, improper lubrication, dirt and excessive ball-bearing fits, and bump and unbalance will cause noise.

Slip frequency noise is caused by an uneven air gap, which may be caused by improper assembly, bending of the shaft due to unbalance, or excessive bearing clearance.

Another type of noise is caused by magnetic forces in the air gap setting up vibration in the motor frame or stator yoke. The cause may be due to improper choice of rotor slots, and to a weakness in the frame or stator yoke.

Ventilating fans in the motor may cause a siren effect due to close clearance between the end of blade and ventilating holes or noise may result from a high velocity of the air passing through the ventilating holes.

All materials should be analyzed from a noise producing and carrying standpoint.

The appliance to which the motor is mounted may act as a sounding board and magnify the noise. A resilient type of mounting is then desirable. This will prevent transmission of the noise through the appliance and also prevent the motor noise from being transmitted through the floors and walls of the house.

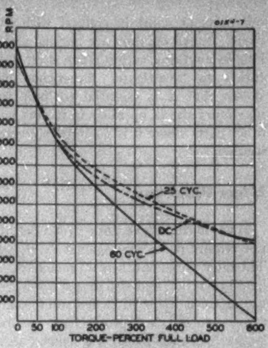

Figure 7. Speed-torque characteristics of a high-speed universal-type motor

Safety

The motor and appliance must be so protected that the user cannot receive injuries from either the electrical or mechanical parts. This means covering electrical circuits and contacts, properly strain-relieving cords, provide proper insulation and sufficient clearance between the frame and live parts, as well as safety releases, such as now provided on motor-driven clothes wringers. Motors open to view and accessible should have the ventilating holes or other openings in the motor of such size that a small child cannot stick its finger into the hole and have it injured by the ventilating fan or mov-

ing parts or come in contact with live parts. Small children are curious and a hole in anything within reach is an invitation to investigate. Experience has shown that it is essential to limit the maximum size of openings in motors and other parts where it is possible to receive injuries.

Motor Protection

Some motors have duty cycles that do not require protection against overloads. The duty cycles of others do require overload protection and also protection where the motor is liable to locked rotor conditions. Adequate protection assures longer life to the motor and reduces service calls to a minimum. Where overloads are infrequent, overload protection will make it unnecessary to design the motor to withstand the temperature encountered at these overloads and will have considerable bearing upon the temperature rating. In most cases "automatic reset" protection devices are used. However, there are some applications and localities that require "manual reset" protective devices.

Appearance

Good appearance is essential to the popular acceptance of any appliance. It is therefore necessary that the motor and appliance design be so co-ordinated that it will be acceptable as a finished product and will blend into the surrounding of the kitchen or any other part of the home in which the appliance will be used.

About 1929, considerable impetus was given to industrial art, which was no doubt due to the interest, of such artists as Maxfield Parrish, in the streamlining of airplanes, high-speed trains, and automobiles. However, it took several years before some of these ideas really approached streamlining. It was found that this idea not only increased the efficiency by cutting down air friction but greatly improved the appearance. Industrial artists have applied art to motored and other appliances, and have contributed much to the improved appearance and popular acceptance of these appliances.

Such appliances as fans, food mixers, and vacuum cleaners are often given a streamlined appearance. This not only helps the air stream some, in the case of the complete fan, to have the motor streamlined, but streamlining the base as well gives the whole fan the appearance of smoothness in operation. There is no functional improvement to be gained in streamlining a vacuum cleaner or food mixer but it does help the appearance considerably. Incidentally, it helps cost in some cases by giving more draft to drawn or cast parts.

The design of modernized kitchens has caused a further improvement in appearance of refrigerators, washing machines, ironing machines and dish washers, so that they will blend into the kitchen as though they were built into it with the cupboards, electric range, etc. Food mixer finishes have been changed to line up with the finishes of the above appliances.

Air-conditioning equipment, unit heaters, fans, etc., are designed to blend with the woodwork and furnishings of most homes.

In many cases, such as in washing machines, dish washers, open-type refrigerators and air-conditioning units, the artist can design good appearing covers or aprons for the complete equipment, or the open-type unit is assembled within the cabinet of a refrigerator. This makes it possible to use standard type motors.

It is apparent that to obtain the maximum in utility and appearance, the design engineer and artist must co-ordinate their efforts so that the proper functioning of the appliance is not jeopardized. However, it may mean ingenious design on the part of the design engineer to preserve a very desirable art design.

Weight, Size, and Material

Weight, size and materials should be considered together. The performance expected and temperature, open or enclosed, determine the size and weight of the stator and rotor. General practice with standard motors is to use a steel frame and cast-iron brackets. If the application warrants the expense of new tools, the weight of these parts may be reduced by die casting them with zinc or aluminum. Magnesium is gaining in popularity but there are certain precautions necessary in machining. Care must be exercised in the decision to die-cast these parts as there may be a resulting increase in noise.

For some built-in motors, die castings may be adaptable with less possibilities of noise because of the additional material in the appliance. At the same time there is the possibility of creating a sounding board effect. Hermetically sealed compressor motors as a rule use cast-iron housing as that material appears to be best suited to the application.

In portable appliances it is desirable to use die castings of any one of the three materials mentioned above, or pressed parts using steel or aluminum, to reduce weight and costs.

Synthetic materials can be molded into frames and brackets or in combinations for the small appliance motors, such as hand vacuum cleaners, portable drills, fans and electric razors. These materials will cause some reduction in noise.

The housing and other parts of the appliance in all cases must be sufficiently well built to withstand the abuses to which it will be subjected without distortion or breakage.

Appearance may have some bearing upon the type of material to be used. For instance, a smooth surface is not obtainable with cast iron except by expensive polishing methods, whereas die casting and pressed metal parts are smooth and can be given a good finish by painting, plating or by polishing in the case of aluminum. Synthetic materials can be dyed; therefore, requiring no extra finish.

Cost

Before any appliance is marketable, the cost must be at a satisfactory figure and at the same time make a profit. Some appliances may be designed for cost at the expense of quality and reputation. More brains and proper manufacturing facilities can co-operate to produce low-cost high-quality appliances.

Serviceability

The functional service and life of the motor and appliance will depend upon the thought given to the design factors mentioned and the application of them. The expected life of the appliance will more or less establish the degree of quality in many items. However, some elements, if they are to function properly at all, will insure long life. All possible effort should be made to eliminate service troubles, but make servicing easy to do, if it is necessary.

Standards

Recognition and application of standards established by American Standards Association, AIEE, NEMA, Underwriters' Laboratories, trade organizations, power companies and the various recognized testing agencies is necessary to the successful and accepted design.

Conclusions

An outline of the principal design factors involved in domestic motored appli-

Single-Phase Motor Theory—a Correlation of the Cross-Field and Revolving-Field Concepts

C. T. BUTTON
ASSOCIATE AIEE

Introduction

THE revolving field theory of single phase induction motor operation resolves the total flux crossing the air gap into two components rotating in opposite directions but constant in magnitude. The cross field theory resolves the total flux into two components of varying magnitude but constant direction with reference to the stator.

The cross field and revolving field theories have been developed by H. R. West[1] and Wayne J. Morrill,[2] respectively, in a complete and analytical manner. From the standpoint of the concepts involved and their final utility, each of these presents certain difficulties. The objective of this paper is to utilize and coordinate both fundamental methods of analysis. A new treatment is used, however, which does not follow the detailed methods or type of development previously used for either theory.

While it is necessary to treat certain factors in an idealized manner, the effort is made to consider a single phase induction motor as it actually is, rather than to say arbitrarily that it is equivalent to some fictitious circuit or other mechanical arrangement as is done with some other theories.

The discussion herein will start with the general expression for voltage induced in a coil rotating in a single phase field (periodically reversing but not rotating).

A two pole motor will be considered throughout for simplicity.

A list of symbols used will be found at the end of the paper.

Rotor Voltage

In a single phase induction motor, there is in practice generally a rough approximation to sinusoidal distribution of flux around the air gap at any instant. In figure 1, it is assumed that flux density is uniform along the X–X axis. The coil has no magnetic core and is simply turning in the field shown. Along the circle traced by the ends of the coil, the flux distribution will then be sinusoidal at any instant.

The flux through the coil will be

$$\phi_c=\phi_M \sin \omega t \cos \theta \tag{1}$$

$$=\phi_M \sin \omega t \cos (p\omega t+\alpha) \tag{2}$$

$$=\phi_M \sin \omega t (\cos p\omega t \cos \alpha - \sin p\omega t \sin \alpha) \tag{3}$$

$$=\frac{\phi_M}{2}\{\cos \alpha[\sin (1+p)\omega t+\sin (1-p)\omega t]+ \sin \alpha[\cos(1+p)\omega t-\cos (1-p)\omega t]\} \tag{4}$$

$$=\frac{\phi_M}{2}\{\sin [\alpha+(1+p)\omega t]-\sin [\alpha-(1-p)\omega t]\} \tag{5}$$

$$=\frac{\phi_M}{2}\{\sin [(2-s)\omega t+\alpha]+\sin (s\omega t-\alpha)\} \tag{6}$$

Voltage in coil $= \dfrac{d\phi_c}{dt}$ (times a constant which is here neglected)

$$=\frac{\phi_M}{2}\{(2-s)\omega \cos [(2-s)\omega t+\alpha]+ s\omega \cos (s\omega t-\alpha)\} \quad (7$$

---

ances has been given with the hope that it will help to organize the thinking of the design engineer and assist him in the procedure of a design.

It would be desirable to give a detailed treatise on the design of each appliance but the subject is of such importance that each appliance would require an individual paper to do it justice. Each factor that has been mentioned and discussed involves years of experiences, and has been the subject of many individual papers. It is well worth while for both the motor and appliance design engineer to review the papers presented at the AIEE winter convention in New York, January 1939, the summer convention in June 1940 at Swampscott, Mass., and others (1 to 10 inclusive, Bibliography). Also AIEE and Underwriters' Laboratories' Standards are of interest (11–12 Bibliography).

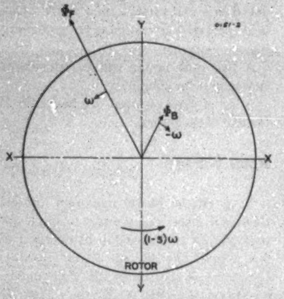

Figure 2. Axes X–X and Y–Y fixed with reference to stator

It is seen that this expression for voltage is precisely what we would have if the single phase field were replaced by two rotating fields of constant magnitude $\phi_M/2 = 1/2$ the maximum value of the single phase field, and each rotating in opposite directions with a velocity of ω radians per second. It can be seen by inspection that these two hypothetical flux vectors are together the vectorial equivalent of the single phase field.

It should be kept clearly in mind just what expression (7) represents. It is the voltage in any rotor turn or single conductor coil due solely to the primary flux (not including voltage due to flux which may exist in the axis in quadrature with the stator poles, and not including that due to leakage flux or resistance drop). In other words, this would be the voltage in a rotor turn consisting of two diametrically opposite rotor conductors, if this turn were open circuited at some point, and no current flowed in this turn nor in any other rotor conductors.

Now with the normal closed circuit rotor squirrel cage, and rotor current flowing, the rotor currents will produce a cross field or quadrature flux in the *X–X* axis. The evaluation of this cross flux becomes the really complex matter in the analysis. The following factors will be listed to show just why it is so involved:

(1). The rotor conductor exciting voltage: This is shown by equation 7. It has two frequencies, each varying with slip, and is different at any instant for each conductor occupying a different angle α.

(2). The rotor conductor current: There will be a rotor current component for each existing voltage component, the magnitude and phase angle of which will be determined by the rotor impedance for the particular frequency of the component in question.

(3). Angular velocity of rotor: The rotor is a moving object; and the angular position of a given conductor will be considerably different at the instant when one voltage component is maximum and the instant when the current due to that voltage is maximum. This fact is completely forgotten in the usual simple textbook "explanation" of the single phase induction motor.

(4). Effect of rotor current on total flux: The existence of the rotor current results in a complex magnetomotive force producing flux in the cross field axis. This flux may be regarded as unbalancing the relative values of the forward and backward rotating field components, tending toward the production of a pure constant forward rotating field as will be discussed in detail later.

It is then evident that we have a mechanism involving a number of interdependent variables; and if an attempt is made to be scientifically precise and to neglect no detail affecting motor performance, and to proceed to set forth expressions for complete rotor currents and voltages, all flux values, and final characteristics such as torque at any given slip in terms of motor constants, the task becomes extremely formidable even to those familiar with motor theory in general.

Referring again to expression 7, it is evident that the first component of voltage may be regarded as that due to the backward rotating flux vector (of the revolving field theory), and the other (slip frequency) component is due to the forward rotating field. Only under open circuit rotor conditions or at standstill, in general, are these two flux components equal ($\phi_M/2$). Attention is here called to figure 2.

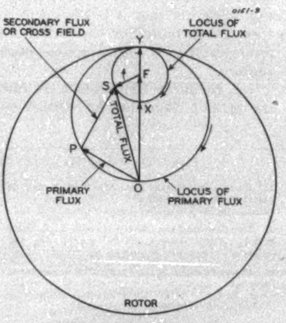

Figure 3. Condition at synchronous speed. Axes fixed with reference to rotor

$$OY=\phi_M=\phi_Y \text{ max}$$
$$OP=\phi_Y$$
$$OX=\phi_{X'}=\phi_X \text{ max}$$
$$PS=\phi_X$$
$$OF=\phi_F$$
$$FS=\phi_B$$
$$\overrightarrow{OS}=\overrightarrow{OF}+\overrightarrow{FS}=\overrightarrow{OP}+\overrightarrow{PS}$$

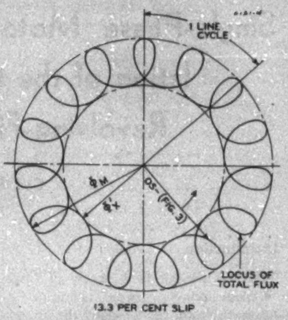

Figure 4. Idealized flux locus of single-phase induction motor under load. Axes fixed with reference to rotor

There are then actually two voltage components in the conductors of the practical rotor, as follows:

$$e_F=\phi_F s\omega \cos (s\omega t-\alpha) \text{ (constant omitted)} \quad (8)$$

$$e_B=\phi_B(2-s)\omega \cos [(2-s)\omega t+\alpha] \quad (9)$$

Now at synchronous speed $s=0$ and $e_F=0$. It is therefore certain that the cross field which exists at synchronous speed is produced by the current resulting from e_B.

Magnetizing Current in Rotor Producing Cross Field

The rotor current due to e_B will be e_B/Z_B, and lagging behind the voltage e_B by an angle whose cosine is R/Z_B. The in-phase component of this current is

$$\frac{\phi_B R}{Z_B^2}(2-s)\omega \cos [(2-s)\omega t+\alpha] \quad (10)$$

The "wattless" component of the current due to e_B will be

$$\frac{\phi_B X_B}{Z_B^2}(2-s)\omega \sin [(2-s)\omega t+\alpha] \quad (11)$$

The flux per square inch in the *X–X* axis is the product of the magnetomotive force and the permeance per square inch. Now if the permeance per square inch is constant, each increment of magnetomotive force multiplied by the area it encloses projected in a plane perpendicular to the *X–X* axis would produce a proportional increment of flux in that axis. For convenience we may then refer to the product of magnetomotive force and its enclosed area thus projected as a "magnetizing effect."

In developing the equations for rotor voltage and current a coil was considered;

this coil lying in a plane which rotated about a line within the plane and perpendicular to the main field flux. In a two pole motor, two rotor bars diametrically opposite with the connecting end rings may be considered as a single turn coil. If the total number of bars or conductors in the rotor is N, there will be a total of $N/2$ turns (or single turn coils) in the rotor. Since the angular conductor density is $N/2\pi$, if equation 11 is multiplied by $\sin\theta(N/2\pi)d\alpha$ and integrated from 0 to π, this will include the projected magnetomotive force of every turn in the rotor. The cross field magnetizing effect of the current component given by equation 11 is thus determined as follows:

$$\int_0^\pi \frac{\phi_B X_B}{Z_B^2}(2-s)\omega \sin[(2-s)\omega t+\alpha]\times \sin\theta\frac{N}{2\pi}d\alpha \qquad (12)$$

$$=\int_0^\pi \frac{\phi_B X_B N(2-s)\omega}{2\pi Z_B^2}\sin[(2-s)\omega t+\alpha]\times \sin[(1-s)\omega t+\alpha]d\alpha \qquad (13)$$

$$=\int_0^\pi \frac{\phi_B X_B N(2-s)\omega}{4\pi Z_B^2}\{\cos\omega t- \cos[(3-2s)\omega t+2\alpha]\}d\alpha \qquad (14)$$

For the integral, with α varying from 0 to π, the second factor or negative quantity in (14) becomes zero, and the magnetizing effect in the X–X axis due to the rotor current of equation 11 is

$$\frac{\phi_B X_B N(2-s)\omega}{4Z_B^2}\cos\omega t \qquad (15)$$

The corresponding integrated magnetizing effect due to the in-phase current component of expression 10 is

$$-\frac{\phi_B N\omega(2-s)R}{4Z_B^2}\sin\omega t \qquad (16)$$

The cross-magnetizing effect of the slip-frequency rotor current is similarly determined as follows, considering first the reactive component:

$$\int_0^\pi \frac{\phi_F X_F}{Z_F^2}s\omega\sin(s\omega t-\alpha)\sin[(1-s)\omega t+ \alpha]\frac{N}{2\pi}d\alpha \qquad (17)$$

$$=\int_0^\pi \frac{\phi_F N\omega s X_F}{4\pi Z_F^2}\{\cos[(2s-1)\omega t-2\alpha]- \cos\omega t\}d\alpha \qquad (18)$$

$$=-\frac{\phi_F N\omega s X_F}{4Z_F^2}\cos\omega t \qquad (19)$$

Similarly, the magnetizing effect of the slip-frequency rotor current in phase with the forward flux is

$$\frac{\phi_F N\omega s R}{4Z_F^2}\sin\omega t \qquad (20)$$

The total magnetizing effect or effective rotor magnetomotive force in the X–X axis is then

$$\phi_B(F_1'-jF_1)-\phi_F(F_2'-jF_2) \qquad (21)$$

where

$$F_1=\frac{N\omega(2-s)^2X}{4[R^2+(2-s)^2X^2]10^8}$$

$$F_1'=\frac{N\omega(2-s)R}{4[R^2+(2-s)^2X^2]10^8}$$

$$F_2=\frac{N\omega s^2X}{4(R^2+s^2X^2)10^8}$$

$$F_2'=\frac{N\omega sR}{4(R^2+s^2X^2)10^8}$$

(The signs in equation 21 should be changed throughout to be mathematically correct as may be observed. This may be done if it is borne in mind that the j factors represent magnetomotive force components in strict time quadrature with the main flux and really determine the relative direction of the cross field. However, equation 21 is written as given to emphasize that the rotor current due to ϕ_B is primarily responsible for positive cross field, and the rotor current due to ϕ_F subtracts from it. No damage is done in subsequent developments by these changes in sign.)

The voltage constant 10^{-8} has been introduced, and the substitutions of $R+j(2-s)X$ for Z_B, and $R+jsX$ for Z_F have been made. Also the time phase factors $\sin\omega t$ and $\cos\omega t$ are dropped, for the sake of brevity.

The revolving field concept visualizes two rotating flux vectors as shown by figure 2. They add in the Y–Y axis to become identical with the mutual flux ϕ_M; and they subtract in the X–X axis to determine the net cross field flux ϕ_X. The cross field by this assumption is maximum at the instant ϕ_Y is zero. The flux in the two axes are thus in both space and time quadrature. Unquestionably in the practical case there are irregularities or harmonics; and also undoubtedly the flux in the X–X axis is not precisely zero at the instant that perpendicular to it is maximum. In any theory however ideal concepts are stated in order that practical mathematics may apply in as simple a manner as possible. The practical problem is to so evaluate the ideal quantities that the calculated results on that basis are within usual limits of experimental accuracy.

The rotor may be regarded as an inductive cylinder which tends to maintain constant flux through itself. As it rotates the rotor flux is forced by the primary magnetomotive force to be maximum at the instant ϕ_Y is maximum. The inductive effect of the rotor prevents this flux from dying to zero when the primary flux is zero, except at standstill. The minimum rotor flux is in the cross-field axis. (If its magnitude were greater than ϕ_M, the backward flux would be negative and no net magnetomotive force would be available to produce positive cross flux.)

The condition at synchronous speed for the flux variation through the rotor is shown by figure 3. Vector FS is the backward rotating flux, and rotates at twice synchronous speed (with respect to the rotor). Vector OF is the forward rotating component, and of course at synchronous speed is fixed and constant with respect to the rotor. OX is the maximum value of cross field flux.

Figure 4 shows the total flux locus with respect to the rotor at a given slip. The locus of total flux traversing the rotor describes a hypotrochoidal curve with respect to it.

In the Y–Y axis the effective rotor ampere turns due to forward and backward rotating currents add instead of subtract as in equation 21; and are balanced by component parts of the primary current. In the X–X axis, however, they must mutually approximately cancel except for that residual magnetomotive force necessary for the cross field.

As the forward flux progresses from the Y–Y axis to the X–X axis, the slip-frequency rotor current at the Y–Y axis changes from the in-phase value through the maximum to the reactive value. Thus the angle of the flux vector ϕ_F at the instant the forward current is maximum at the Y–Y axis depends on the impedance angle of slip-frequency current. The cross-field integrated magnetomotive force of the slip-frequency current is a periodic reversing quantity; and it is out of phase with that due to the "backward" current since the impedance angles of the two are only equal at zero speed.

Figure 5 shows schematically the flux vectors ϕ_F and ϕ_B at an instant just before the flux through the stator winding is maximum. Conductors (1) form a turn in which the rotor current due to ϕ_F is maximum, and conductors (2) carry maximum rotor current due to ϕ_B. Angle (2) will be greater than angle (1), as the frequency of the current due to ϕ_B is greater than that due to ϕ_F.

The magnetizing effect in the X–X axis in time phase with the primary flux is given by adding expressions 16 and 20. The basic hypothesis used herein assumes that this cross field in phase with the main field is negligible.

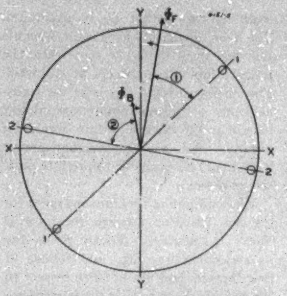

Figure 5. Location of maximum forward and backward rotor current. Axes fixed with reference to stator

The magnetizing effect in the X–X axis in phase quadrature with the primary flux is given by adding expressions 15 and 19.

A hypothetical rotor with zero leakage reactance would be ideal for producing torque in a polyphase motor. In a single-phase stator, such a rotor would not produce a cross field in time quadrature with the main field but would merely in effect shift the axis of the main field. Hence no motor action would result.

A hypothetical rotor with zero resistance and 90° rotor impedance angle would be ideal for setting up a cross field in time quadrature, but would produce no torque.

As a general statement then it may be said that the reactive component of rotor current establishes the rotating field and the in-phase component produces torque. The in-phase component will, however, have an influence on the total flux, which is taken into account in a manner which is sufficiently accurate for practical purposes by the sine factor in equation 23 below.

Determination of Forward and Backward Rotating Flux Magnitudes

The respective values of the forward flux ϕ_F and the backward flux ϕ_B are determined as follows:

(1). The sum of the voltages they induce in the stator winding is equal to the line voltage minus primary impedance drop. (See equation 22.)

(2). The difference between these two fluxes is the cross field. (See equation 23.)

$$\sqrt{2}(E-i_1Z_1)=(\phi_F+\phi_B)T_{\text{eff}}10^{-8} \quad (22)$$

where T_{eff} is the total primary turns (for a two-pole motor) multiplied by the distribution factor. The latter is $\pi/4$ for the ideal case of a winding with sinusoidal distribution. (This corresponds to $N/4$ or 1/2 the total rotor turns, which are linearly distributed.)

$$(\phi_F-\phi_B)\sin\left[\frac{\tan^{-1}\frac{sX}{R}+\tan^{-1}\frac{(2-s)X}{R}}{2}\right]=$$

$$\{\phi_B(F_1'-jF_1)-\phi_F(F_2'-jF_2)\}\frac{\phi_{M0}}{\sqrt{2}i_mT_{\text{eff}}} \quad (23)$$

Let

$$\gamma=\frac{\phi_B}{\phi_F}$$

From (23)

$$\gamma=\frac{\phi_{M0}\sqrt{F_2'^2+F_2^2}+\sqrt{2}i_mT_{\text{eff}}\sin\epsilon}{\phi_{M0}\sqrt{F_1'^2+F_1^2}+\sqrt{2}i_mT_{\text{eff}}\sin\epsilon} \quad (24)$$

The primary current i_1 of (22) flowing through the primary turns (effective value) overcomes the rotor magnetomotive force by an amount necessary to produce the existing mutual flux.

$$i_1=i_m\frac{\phi_F+\phi_B}{\phi_{M0}}+[\phi_B(F_1'-jF_1)+$$

$$\phi_F(F_2'-jF_2)]\frac{1}{\sqrt{2}T_{\text{eff}}} \quad (25)$$

Equation (22) may be modified to the following:

$$\frac{E-i_1Z_1}{E-i_mZ_1}=\frac{\phi_F+\phi_B}{\phi_{M0}} \quad (26)$$

From (25) and (26)

$$\phi_F=\frac{\phi_{M0}}{1+\gamma+\frac{Z_1\phi_{M0}}{\sqrt{2}ET_{\text{eff}}}\times\sqrt{(F_1'\gamma+F_2')^2+(F_1\gamma+F_2)^2}} \quad (27)$$

The treatment of these last equations in algebraic rather than vectorial fashion is an approximation justified for most practical purposes.

Motor Torque

For any slip s, we now have the forward rotating flux vector ϕ_F and the backward vector ϕ_B. Assuming that one is not interested in the instantaneous torque (or the pulsating component), the total or average torque is

$$T_{\phi F}+T_{\phi B}$$

The second factor, torque due to backward rotating flux, is inherently negative, and hence total average torque is the difference of these two component parts. Each torque component may be calculated as for a polyphase motor where given the flux, slip, and rotor constants—as follows.

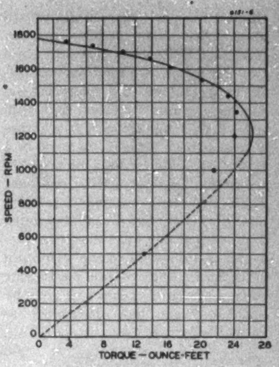

Figure 6 (Curve 1). Speed versus torque

Solid curve—test
Dashed curve—test extrapolated
Circles—calculated

Note: No allowance in calculated values for friction and windage

We have the rotor voltages in equations 8 and 9, whence the in-phase rotor current will be

$$\phi_FG_Fs\omega\cos(s\omega t-\alpha)+\phi_BG_B(2-s)\omega\times\cos[(2-s)\omega t+\alpha] \quad (28)$$

where the conductance $G_F=\frac{R}{R^2+s^2X^2}$

and $G_B=\frac{R}{R^2+(2-s)^2X^2}$

The in-phase component of slip-frequency current is maximum at any instant in the conductor which is at the point of the air gap carrying maximum (forward) flux. Both the forward flux density and the in-phase slip frequency current magnitude will vary around the air gap at any instant as $\cos\delta$; δ being zero where ϕ_F is maximum.

The forward flux per unit length of air gap (=density × length of rotor) at the point where ϕ_F is maximum is ϕ_F/d—where d is the diameter of the rotor. The torque being a tangential force (which is the product of flux density and current) multiplied by the lever arm $d/2$; then the torque due to two rotor conductors forming a turn at the diametrically opposite points of maximum flux density will be found by multiplying the in-phase current by the total forward flux ϕ_F. In symbols, the above may be stated in abbreviated form

$$T=\frac{\phi_F}{d}\times I\times\frac{d}{2}\times 2=\phi_F\times I$$

(for the two conductors or one turn).

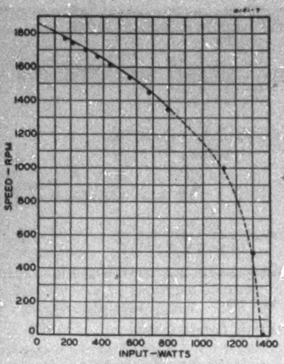

Figure 7 (Curve 2). Speed versus watts

Solid curve—test
Dashed curve—test extrapolated
Circles—calculated

The quantity I is the in-phase "forward" current in the rotor bar in which it is maximum at any instant.

The torque due to ϕ_F for one rotor turn then is

$$\phi_F^2 G_F s\omega \cos^2\delta = \frac{\phi_F^2 G_F s\omega}{2}(1+\cos 2\delta) \qquad (29)$$

Multiplying by $\dfrac{N10^{-8}}{2\pi}\,d\delta$, and integrating from $\delta=0$ to $\delta=\pi$,

$$T\phi_F = \frac{\phi_F^2 N s\omega R}{4(R^2+s^2X^2)10^8} = F_2'\phi_F^2 \qquad (30)$$

Similarly, the torque due to ϕ_B is

$$T\phi_B = F_1'\phi_B^2 \qquad (31)$$

Total average torque is

$$K(F_2'\phi_F^2 - F_1'\phi_B^2) \qquad (32)$$

K is a constant which has the value 0.7376×10^{-8} to reduce to pound-feet.

For a motor having more than two poles, expression 32 will be modified as indicated in Appendix I.

Conclusions

Present methods of calculating the performance of single-phase induction motors are quite tedious, and probably do not convey to the mind of the practical engineer a logical concept of the operation of the motor such as is the case with generally used methods of polyphase motor design calculation. It seems desirable to have a unified and co-ordinated theory for single phase induction motors including formulas which are simplified as much as possible (with justifiable approximations) and which convey unabstruse concepts. The formulas developed may be used as the basis of a routine calculation procedure.

An advantage of formulas of this type is that they deal with real values—actual rotor current in a rotor bar in amperes, and so on. The value of rotor impedance does not change in using the same rotor with two different stator windings for example, as it does when equivalent primary values are used. Flux densities in the cross field axis and other similar values are explicitly evident.

In applying the equations developed, it is necessary first to determine motor constants by established methods (primary impedance, magnetizing current and flux value with open-circuited rotor, and effective rotor resistance and reactance for a turn consisting of two rotor bars 180° apart with connecting end rings common to all turns).

Symbols and Conventions Followed in Text

Primary flux $=\phi_Y=\phi_M \sin\omega t$

This is the total flux component in the Y–Y axis of figure 1, common to stator and rotor. It may also be called the mutual flux.

"Total flux" is regarded as $\overrightarrow{\phi_Y}+\overrightarrow{\phi_X}$ where ϕ_X is the flux in the X–X axis and is referred to as the cross field. ϕ_X' is further taken as that magnitude of flux in the X–X axis, which exists at the instant ϕ_Y is zero. ϕ_X is therefore at any instant $\phi_X' \cos\omega t$.

p = per unit synchronous speed = rpm ÷ synchronous speed $=1-s$ where s is per unit slip
$\omega=2\pi f$ where f is line frequency
R = rotor resistance
X_F = rotor reactance at frequency sf $=sX$
$X_B=(2-s)X$ = rotor reactance at frequency $(2-s)f$
$Z_F=R+jsX$ = rotor impedance at frequency sf
$Z_B=R+j(2-s)X$ = rotor impedance at frequency $(2-s)f$
Z_1 = primary or stator impedance*
ϕ_c = flux through coil of figure 1
θ = angular position of coil of figure 1 at any instant $=p\omega t+\alpha$
α = initial angle of coil when flux ϕ_Y is zero
ϕ_F = forward rotating flux component
ϕ_B = backward rotating flux component
ϕ_{M0} = maximum value of primary flux ($Y-Y$ axis) with rotor open-circuited (standstill with zero rotor current)
T = total primary (stator) turns
T_{eff} = total primary turns multiplied by distribution factor*
N = total secondary (rotor) bars or conductors*
E = line volts, rms*
e_F and e_B = rotor voltages due to forward and backward flux components (respectively) cutting rotor conductors
I_1 = primary-current (rms amperes) at any slip s
i_m = primary magnetizing current (rms) with open circuit rotor $=i_c-ji_m'$
δ = angle measured around air gap from point where revolving flux is maximum at any instant (stator angle measured from traveling reference)
ϵ = angle which is one-half the sum of the two rotor impedance angles at frequencies of sf and $(2-s)f$ respectively

*Multiply by $2/P$ where P is number of poles. See appendix I.

Appendix I (Notes)

Calculation methods now in general use refer rotor impedance values to the primary. The values of R and X used herein may be obtained from such primary equivalents by multiplying by $N/(4T_{eff}^2)$. (Multiplying equivalent primary impedance of rotor by $1/T_t^2$ would give total rotor impedance considered as a single turn of all rotor copper in parallel. Multiplying this by $N/4$ would give the effective impedance of a single rotor turn as considered herein.) Rotor impedance values may also be obtained from standstill test. Rotor effective ampere turns = primary effective ampere turns less magnetomotive force for standstill flux. This determines maximum rotor current I. Rotor loss $= I^2RN/4$ and thus R is determined from standstill watts less primary and core loss at standstill. X may generally be assumed about equal to the primary reactance, multiplied by $N/4\ T_{eff}^2$. The standstill flux produces a voltage IZ in one turn of the rotor completely linking it, where $Z=R+jX$.

For a series-connected motor with four poles, the formulas may be applied using half the total primary turns, half the rotor bars, half the primary impedance, and 50 per cent line voltage. The final torque as determined by (32) will then be multiplied by four, since half the motor has been considered and also the rotor radius is twice that of a two-pole motor for which the above half-values would represent the complete motor. Or in general terms, in applying the formulas, E, N, T, and Z, may be multiplied by $2/P$ where P is the number of poles in the motor; and the torque will be found by multiplying the expression for torque by $(P/2)^2$.

Introduction

THIS paper presents the design of a condenser type indicator and associated electrical equipment, together with the technique of measuring pressures in internal-combustion engines.

The term, pressure indicator, in this paper will be used to refer to the pressure-sensitive element, and not to the type of amplifying and recording systems used in conjunction with the pressure elements.

The selection of an electrical pressure indicator for engine work may involve a choice of several kinds of pressure-sensitive devices, as well as many types of electrical circuits and recording methods. However, it is beyond doubt that no single available combination of pressure indicator and associated electrical equipment meets all the demands of complete engine-pressure analysis. Nevertheless, with a fairly complete knowledge of the defects and limitations of the various kinds of indicators available, the instrument and engine engineer may successfully cope with most of the problems of pressure measurements.

Before discussing the characteristics of the various types of pressure elements, it might be well to consider the important requirements of an ideal engine indicator and its associated amplifying and recording equipment.

1. The ideal indicator must give a linear and undistorted response to any instantaneous pressure encountered in the engine to be studied.
2. The natural frequency of the indicator must be well above any frequencies to be measured.
3. It must have an accurate predetermined calibration that will not be affected by temperature, time, fatigue, or external forces such as vibration or shock.
4. It must be insensitive to all forces except the pressures applied to the diaphragm, that is, it must not pick up engine vibrations.
5. It must be capable of indicating an atmospheric or any other desired pressure datum line.
6. It must be small in physical structure in order that it may be easily installed in modern engines.
7. It must be reasonably simple to operate.
8. It must be capable of recording pressures during a single engine explosion.

At the present time, no known pressure-indicating equipment meets all of these requirements. Fortunately, however, the engine development engineer can compromise on some of these requirements and still obtain instrumentation which is dependable and useful.

For choice of an electrical pressure indicator capable of measuring pressures for a single engine cycle, the following types have been developed:

1. Resistance-type indicators
   - (a). Carbon stack
   - (b). Carbon granule
   - (c). Solid carbon resistor
2. Piezoelectric crystal-type indicators
3. Magnetic-type indicators
   - (a). Moving diaphragm
   - (b). Moving coil
4. Condenser type indicators

All types of pressure-sensitive units have characteristics which make them useful for certain applications. Likewise, most of these indicators possess characteristics which make their use unsatisfactory for some work. The principal advantages and disadvantages of the various types of indicators and pressure-sensitive devices may be briefly outlined to present their possibilities and limitations for any given application.

1. Resistance-type indicator

Advantages:

No electrical amplifiers are needed to operate a magnetic type galvanometer oscillograph. This is especially true of the carbon stack indicator which may be constructed to have a high-current output.

Disadvantages:

(a). Instability of calibration (particularly under severe conditions)

Figure 4. Water-cooled condenser-plate indicator

(*b*). **Responds to severe vibration**

2. Piezoelectric crystal-type indicator

Advantages:

(*a*). **Highly linear response**
(*b*). **Constancy of calibration**

Disadvantages:

(*a*). **Requires extremely high-gain electrical amplifiers**
(*b*). **Responds to severe vibration**
(*c*). **Extreme care must be taken to minimize leakage in the input circuit of the high-gain amplifier**
(*d*). **In the present state of development, it is unsuitable for low-speed work, static pressure measurements, and for the measurement of extremely low pressures**

3. Magnetic-type indicator

Advantages:

(*a*). **Gives rate of pressure change directly. (A-c impedance bridge circuit gives a pressure-time diagram)**
(*b*). **No mechanical contacts are required between the diaphragm and the electrically sensitive element**

Disadvantages:

(*a*). **A complicated high-gain amplifier is required to accurately integrate the rate of pressure-change response into pressure-time response over the required frequency range**
(*b*). **The present a-c impedance electric circuits for use with magnetic-type indicators do not give accurate reproduction of high-frequency components**

4. Condenser-type indicator

Advantages:

(*a*). **As will be shown in this paper, this indicator lends itself to an exceptionally compact and sturdy construction which is easily serviced, has a high natural frequency, and is relatively insensitive to shock and vibration**
(*b*). **No mechanical contacts are required between the pressure diaphragm and the electrically sensitive element**

Mechanically this indicator offers no disadvantages that are not present in the other type indicators.

The associated electrical equipment for measuring the change in capacity of the indicator may offer certain limitations depending upon the type of circuit used. For example, the electrostatic type of circuit for measuring small changes in capacity has the following limitations: (1) high-gain electrical amplifiers are required, (2) limited low-frequency response, and (3) high-input impedance which makes the electrical amplifiers very sensitive to ignition interference.

Some of these limitations are overcome by the resonance impedance circuit which will now be described in connection with a condenser-type indicator developed in the General Motors Research Laboratories. Limitations introduced are discussed in this paper.

Principle of Operation

Figure 1 shows the general arrangement of the equipment. The indicator illustrated has been drawn in its elementary form for simplicity. Its capacity is formed by the diaphragm and the insulated electrode. This capacity C_3 is a part of a tuned resonant circuit as shown in figure 2 in which L_1C_1 form part of a stable high-frequency oscillator circuit. The tuned circuit, $L_2C_2C_3$ is loosely coupled to a circuit L_1C_1. The high-frequency potential induced in circuit $L_2C_2C_3$ is rectified, and the d-c output current of the rectifier is indicated on a microammeter.

The response of the tuned circuit L_2-C_2C_3 to a constant frequency is shown in figure 3 as a function of the capacity (C_2 plus C_3) of this circuit. This curve is typical of a parallel resonant circuit. Peak output occurs at point *A* when the circuit is tuned to resonate at the oscillator frequency. This circuit is tuned to its operating point *B* by increasing capacitor C_2 until the rectifier meter reads approximately 70 per cent of maximum. Any small change in indicator capacity C_3, due to pressure on the diaphragm, affects the response of the circuit according to the curve of figure 3.

Since the range of capacity change of the condenser-plate indicator is very small, the response of the tuned circuit is limited to a small section such as *B-C* of the response curve. While this section of the curve is not necessarily a straight line, it will be shown later that the output of the detector is approximately linear. The output is amplified before passing to the viewing and recording oscillographs, see figure 1.

In order to accurately reproduce the pressure encountered in engine indicator work, the indicator and its associated electrical equipment should give linear response to frequencies as high as 10,000 cycles per second. This requires an oscillator frequency of 100 kilocycles per

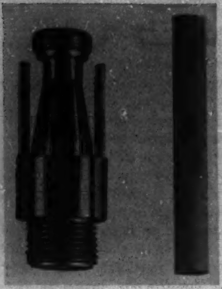

Figure 5 (left)

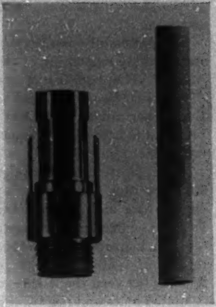

Figure 6 (right)

second or higher to prevent distortion of the high-frequency components. An oscillator frequency of approximately 400 kilocycles per second was selected because reliable circuit components are commercially available in the frequency range of 400 to 500 kilocycles per second.

Mechanical Design of the Indicator

The following mechanical design features are desirable, considering the characteristics of the electrical circuit as well as the indicator applications.

1. The physical dimensions of the indicator must be small enough to facilitate installation on modern engines.
2. The construction must be compact and rigid in order to minimize the effects of severe vibration, that is, the inertia forces must be small.
3. The natural frequency response of the elastic system should be well above any frequency encountered in engine indicator applications. Pressure changes as high as 6,000 cycles per second are common in the combustion chamber of some engines under detonating conditions.
4. The design of the indicator should permit an easy choice of diaphragm thickness to enable measurements over a wide pressure range. To cover the varied requirements of present-day engine research, the range should extend from a few ounces to several thousand pounds per square inch. If the diaphragm thickness is chosen so that its maximum deflection is approximately constant for the maximum pressure change to be measured, in a given application, then the requirements of the associated electrical equipment are much more readily met.
5. The indicator should be constructed so that it can be installed with the diaphragm flush with the walls of the pressure chamber. This type of installation eliminates the possibility of surge effects in connecting passages.
6. Temperature effects should be made as low as possible. Temperature differences, due to changes of engine load and speed, produce a shift in the indicator response. Until a suitable metal is found that will not change its dimensions or elastic properties with temperature, it has been found necessary to provide efficient water cooling.
7. The indicator should be constructed so that it can be readily serviced and assembled.
8. The design should provide adequate electrical shielding combined with a good method of cable connection.

Figure 4 is a cutaway view of the latest type of condenser indicator developed at General Motors Research Laboratories.

The assembly consists of three principal parts: (1) a water-cooled frame and diaphragm, (2) an insulated fixed plate and electrode assembly, and (3) an electrode shield and cable connector.

The frame and diaphragm form an integral unit which is machined from a solid piece of Invar metal. Invar is used to minimize the effect of temperature changes in the diaphragm. Water cooling keeps the temperature of the indicator within the range where the low thermal coefficient of Invar steel is realized.

An important design feature is the water cooling of the diaphragm. After passing through the frame the water flows through a series of interconnected concentric grooves machined on the bottom side of the heavy diaphragm and sealed by a thin disk which is copper-brazed in place, see figure 4. This construction makes the thin sealing disk an integral part of the heavy diaphragm, and thus eliminates any mechanical joints or linkages. The diaphragm is also extremely sturdy.

The fixed-plate and insulated-electrode assembly is made from the mica-insulated center electrode of an aircraft spark plug. This electrode is sturdy and well insulated and has small electrical capacity to the frame of the indicator. Complete electrical shielding is provided by a metal jacket which serves as a unit shield and cable connector as shown in figure 4. In order to minimize extraneous capacity changes such as produced by cable vibration and vibration of parts in the oscillator detector unit, it is desirable to have a large capacity change in the indicator. Since the capacity between parallel plates varies as an inverse function, it is necessary to select a diaphragm thickness so that its movement is limited to approximately 15 per cent of the initial air gap in order to obtain approximately linear response.

Considering the natural frequency of the diaphragm, its elastic properties and limited diameter, a maximum safe dia-

Figure 7

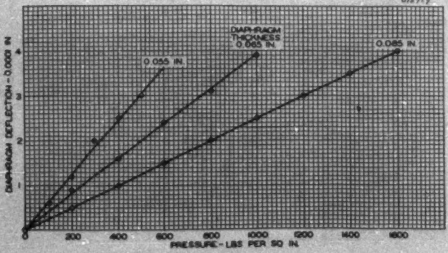

Figure 8 (right)

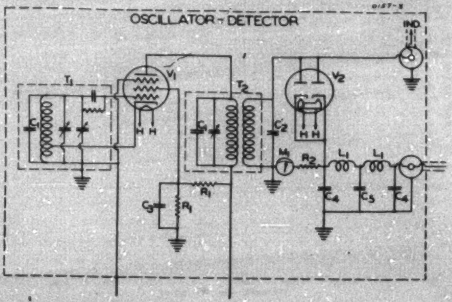

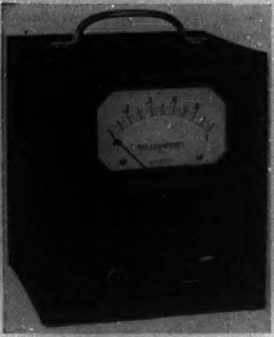

Figure 9

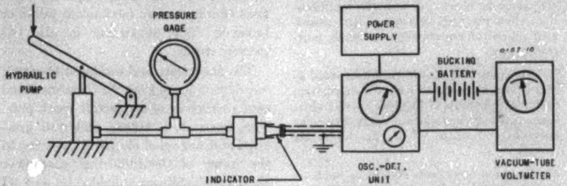

Figure 10

phragm movement of 0.0003 inch was chosen. In order to obtain adequate initial capacity, sensitivity, and linearity with this small movement, an air gap of approximately 0.002 inch was chosen. The initial capacity and sensitivity of the indicator is further improved by the use of a 0.001-mica separator between the plates. This mica also prevents shorting of the plates by minute dust or metallic particles.

For successful operation of the indicator, accurate machining of all parts is essential. The surfaces of the condenser plates must be parallel and separated by the proper amount. It has been found practical to hold the plates parallel within 0.0001 inch.

The indicator shown in figure 4 has a standard 18-millimeter spark-plug thread on the base and a bore diameter of $^7/_{16}$ inch. The fixed plate diameter is held to 0.415-inch in order to clear the root diameter of the $^7/_{16}$-60 tapped hole in the frame. Spacing between the 0.415-inch diameter insulated plate and the $^7/_{16}$-inch bore provides sufficient clearance to assure small capacity between the periphery of fixed plate and the frame. Small capacity in all parts except between the parallel surfaces of the condenser plates is desirable in order to obtain maximum sensitivity. Figure 5 is a picture of an assembled 18-millimeter indicator.

A 14-millimeter indicator, shown in figure 6, has been developed for use in applications where compactness is necessary.

Since it is desirable to limit the movement of the diaphragm to approximately 0.0003 inch, its thickness is determined by the peak pressure to be measured. The curves in figure 7 have been obtained by plotting diaphragm deflection of the water-cooled 18-millimeter indicator versus pressure in pounds per square inch applied to the indicator diaphragm. A suitable diaphragm thickness for any given pressure measurement may be selected by reference to this chart. For example, with peak pressures of 800 pounds per square inch, a diaphragm thickness of 0.065 inch should be used.

Any indicator can be used over a wide range of pressures by changing the gain of the electrical amplifiers. The sturdy diaphragm construction makes it possible for the sensitive indicators to withstand high pressures.

An indicator used in an exhibit at the 1939 New York World's Fair furnishes an example of the ruggedness of this type of construction. Failure occurred after approximately 1,500 hours of operation (about 54,000,000 power strokes) in the combustion chamber of a Cadillac engine. Failure was due to corrosion of the sealing disk.

Electrical Equipment

Oscillator-Detector Unit

A complete schematic diagram of the oscillator-detector unit is shown in figure 8. This circuit corresponds to the skeleton diagram of figure 2. A photograph of the entire unit appears in figure 9.

Tube V_1, in figure 8, and its associated circuits form an electron-coupled high-frequency oscillator. This type of oscillator is used because it provides relatively high output and is inherently stable. The rectifier or diode-detector tube V_2, which is connected as a half-wave rectifier, is coupled to the oscillator through transformer T_2. A microammeter M_1 reads the rectified current flowing through the diode load resistor R_2; therefore, the microammeter reading is an indication of

the output voltage across R_3. A low-pass filter $L_1C_4C_5$, designed to cut off all frequencies above 63,500 cycles per second, removes the oscillator-frequency component from the rectified output voltage.

A concentric cable connects the condenser indicator to the oscillator-detector unit. Since the electrical capacity of the cable forms a part of the tuned circuit in which the indicator is connected, it is apparent that a small change in its capacity will affect the output in the same manner as pressure applied to the indicator diaphragm. Severe vibration of the cable causes small changes in capacity due to the movement of the inner conductor in relation to the outer shield. In order to minimize this effect, the oscillator-detector unit is mounted near the condenser indicator with a short length of low-capacity cable. The diaphragm plate of the indicator is grounded to the engine and fixes the ground point of the oscillator-detector unit. The output voltage developed across R_3 and M_1 in the circuit of figure 8 is at a positive potential when referred to ground.

Figure 15

Static calibration tests were made with a condenser-plate indicator and an oscillator-detector unit to determine their overall sensitivity as well as their linearity of response to pressure. Figure 10 shows the test equipment. A water-cooled indicator of the type shown in figure 4, with a diaphragm thickness of 0.055 inch, was used for this test. At zero-gauge pressure on the diaphragm, the power-supply voltage was adjusted to give a peak oscillator-detector reading of 1.0 milliampere. The detector was then detuned to 0.4 milliampere in successive steps of 0.1 milliampere. At each detector setting, pressure was varied from 0 to 400 pounds per square inch, and the corresponding output voltage measured.

The data plotted in figure 11 show that the output is approximately linear when the detector is operated at initial meter settings of 0.8, 0.7, 0.6, 0.5, and 0.4 milliampere. When it is operated with an initial meter setting of 0.7 milliampere, on the side of the response curve that gives decreasing output voltage with increasing capacity, a pressure change of 400 pounds per square inch gives a 10.5-volt change in the output voltage.

These data show that best linearity of response (over a wide range) is obtained by operating about a point that is approximately 70 per cent of the maximum response as illustrated in figure 3. By operating on the side of the response curve that gives decreasing voltage output with increasing capacity, the nonlinearity of the resonant curve approximately compensates for the nonlinearity of the capacity changes in the indicator.

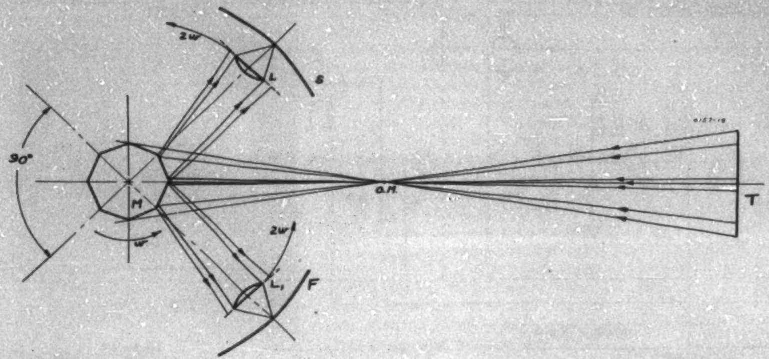

Figure 18

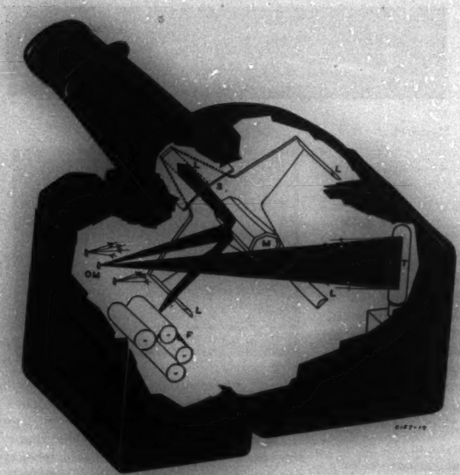

Figure 19

Oscillograph Amplifier

In order to observe or record the output of the oscillator-detector unit under dynamic conditions, the output must be amplified to operate a cathode-ray or a mechanical oscillograph. The schematic diagram of an amplifier built to operate both a cathode-ray and a mechanical oscillograph is shown in figure 12.

The amplifier possesses the following characteristics:

1. Flat frequency response from 4 to 10,000 cycles per second. The low frequency response has been extended to four cycles per second by providing interstage coupling circuits C_5R_8 and C_6R_{10} having high-time constants.

2. A voltage supply in the grid input circuit of the first stage to cancel the initial d-c output voltage of the oscillator-detector and to furnish proper grid bias for the first stage.

3. A power source in the cathode circuit of the second stage to cancel the initial cathode current flowing through the mechanical oscillograph.

Over-all stability of the oscillator-detector and associated amplifier has been improved by using an electronic voltage-regulated power supply. The complete schematic diagram of the indicator, the oscillator-detector, the amplifier, and the regulated power supply appears in figure 13.

For static measurements it is necessary to use a stable d-c amplifier of relatively low gain.

Recording Equipment

For viewing and recording of pressure phenomena in high-speed internal combustion engines, equipment must be used that will respond to the highest frequen-

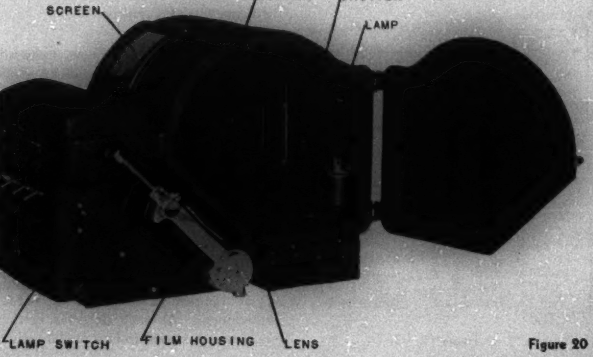

Figure 20

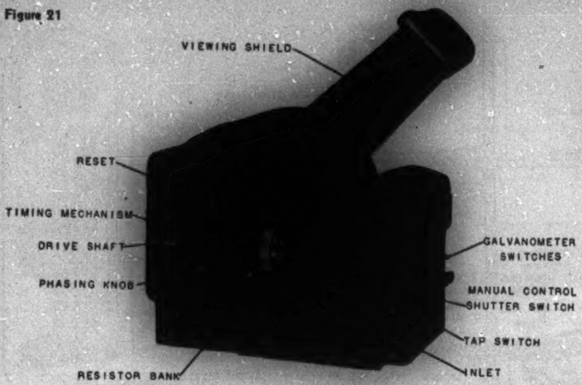
Figure 21



cies to be measured. In general, there are two types of equipment that are practical, namely, cathode-ray and galvanometer oscillographs.

The cathode-ray oscillograph is essentially a voltage-operated device which may have practically unlimited frequency response, whereas, the galvanometer oscillograph is essentially a current-operated device and has a definite limited response. With practical electrical circuits, the frequency response of the galvanometer oscillograph is sufficient for most engine indicator instrumentation. However, for some phenomena such as detonation in a combustion chamber, the use of a galvanometer oscillograph is impractical.

Two methods are available for recording with a cathode-ray oscillograph: (1) by using a moving film to provide for a time axis, and (2) by using stationary film with an electrical time axis.

When an electrical time axis is used, the oscillograph sweep circuit may be synchronized at engine speed by connecting the external synchronizing circuit of the oscillograph to a voltage-impulse arrangement driven by the engine. Either a battery and contactor arrangement as shown in figure 14 or a magnetic impulse generator as shown in figure 15 may be used.

Figure 16 is a pressure card taken in the combustion chamber of a detonating engine by the use of a rotating drum for a time axis. Figure 17 is a similar card taken by stationary film in conjunction with an electrical time axis.

While the cathode-ray oscillograph can be used for recording, it is particularly well adapted for viewing. On the other hand, the mechanical or galvanometer oscillograph is a relatively poor viewing mechanism, but is well adapted for recording.

A multielement mechanical oscillograph has been developed especially for use with engine indicators. The design of this oscillograph includes the following features:

1. Convenience and simplicity of operation.
2. A tungsten-filament light source.
3. An optical system that gives a uniform time axis and permits simultaneous viewing and recording.
4. Revolving short focal length lenses give high photographic speed with stationary film.
5. Four galvanometers may be used simultaneously.
6. Daylight loading and unloading of standard roll film.
7. A rapid film advancing mechanism with automatic spacing and exposure counting device.
8. A device for phasing the oscillograph time axis with the engine crankshaft during operation.
9. A barrel-type shutter with a simple timing mechanism.

Two sketches in figures 18 and 19 show the optical system of the oscillograph. To simplify the diagram in figure 18, the galvanometer mirror, *OM*, is shown acting as a pinhole instead of as a small mirror. The rotating mirror is octagonal and rotates at one-half the angular velocity of the lenses which are four in number. This mirror splits the image of the tungsten filament, *T*, reflecting part of this light to the cylindrical lens *L*, and part to L_1. Each of these two $^{11}/_{16}$-inch focal length lenses receives light from a portion of the filament and forms an image of this portion of the filament on the viewing screen or film. Obviously the length of the image of this portion of the filament depends upon the relative distance of image and object from the lens. A unique and important feature of this oscillograph is the rotating lens arrangement which makes it possible to use short focal length lenses close to the viewing screen and film, resulting in exceedingly fine traces. Since the width of the trace is partly determined by the diameter of the filament, a very fine straight tungsten strip is necessary. Any sagging of the

Figure 22. Phase-changing device

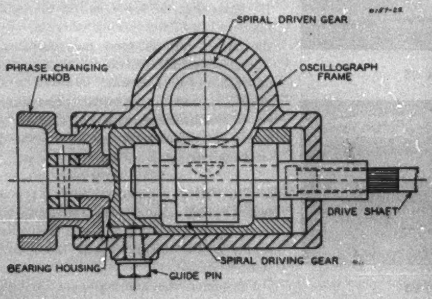


Figure 23

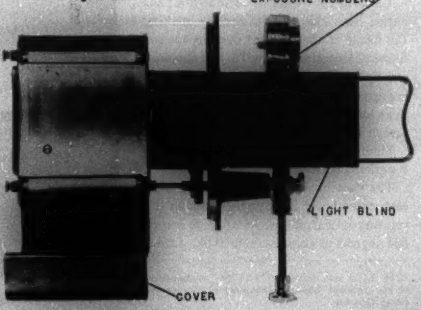

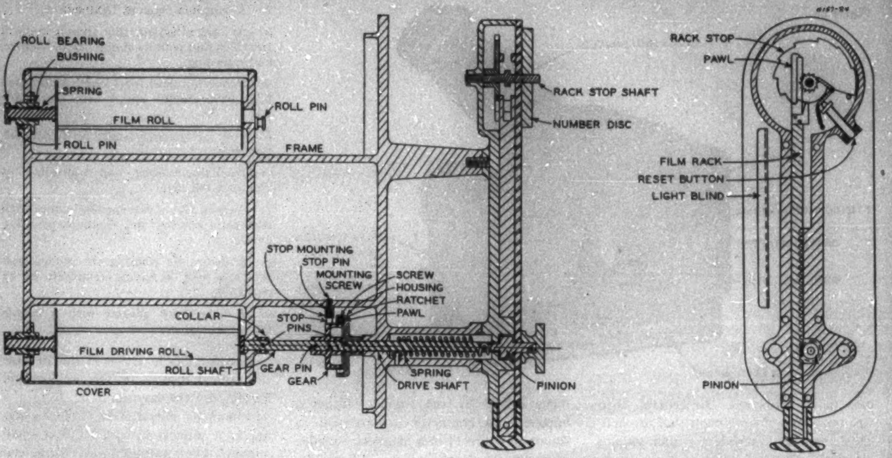

Figure 24

filament in a direction perpendicular to the plane of figure 18 increases the width of the resulting image. Several lamps were tried in an effort to find a suitable filament but since none of the available lamps proved satisfactory, a lamp was designed with a light spring mounted at one end of the tungsten strip.* This type mounting has been successful, as the constant spring tension tends to remove the slack due to expansion when the filament is heated. With the use of this long tungsten filament in place of the carbon arc light employed in former engine oscillographs, the necessity of constantly adjusting the light source is eliminated. The large amount of light, condensed to a very small spot, results in high photographic speed.

It has been shown experimentally that the optical system, as sketched in figure 18 does not introduce an error in the time axis.

Uniform light intensity throughout the entire time axis is obtained by making the image of the filament overlap the cylindrical lenses, see figure 18. In this way the light overlaps the face of the lenses enough to take care of the shifting of the light beam as it leaves the reflecting surface of the rotating octagonal mirror.

Figures 20 and 21 are pictures of the completed oscillograph.

The viewing screen and recording film each extend over 30 degrees of arc in the rotating optical system. In order to record 360 degrees of engine-crankshaft rotation on the 30-degree arc, it is necessary to use a 12:1 reduction gear between the engine crankshaft and the oscillograph. Any desired angle of crankshaft revolution can be viewed or recorded by a suitable gear reduction.

Very often in engine indicator work, it is desirable to study different parts of the engine cycle. To obtain the desired phase of the oscillograph with respect to the phase of the engine crankshaft, some provision must be made so that the phase of the oscillograph may be changed while the engine is in operation. The phase-changing device shown in figure 22 consists of two spiral gears in mesh with their shaft angles at 90 degrees and a method of sliding one of these gears perpendicular to the axis of the other gear. The driving spiral gear is mounted on the oscillograph drive shaft in such a manner that it may be moved back and forth across the mating spiral gear. This sliding movement causes the driven gear which is attached to the oscillograph mirror to revolve, thus changing the phase of the oscillograph with respect to that of the engine. The phase of the oscillograph may be changed with or without the engine running.

Figure 25

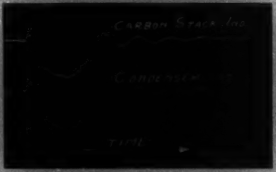

Figure 26

In order to permit continuous viewing, it is necessary that the shutter mechanism does not interrupt the light falling on the viewing screen. An inspection of figure 18 shows that the lower half of the light filament is used for viewing, whereas, only the upper half is used for recording. Therefore a shutter is needed only on the upper half of the filament. A barrel-type shutter is shown in figure 20. The shutter is synchronized with the engine by means of a suitable timing device located on the mirror shaft.

The light intensity is varied to accommodate various engine speeds by a tapped switch which changes the resistance in series with the lamp. A 110-volt d-c supply is used to operate the lamp and shutter circuits.

The camera film housing figure 23, is an

assembly of a light-tight film holder, film indexing mechanism, and light blind.

The film indexing mechanism shown in figure 24 is a rack and pinion drive which advances the film $3^3/_4$ inches for each index, thus giving ten single exposures on a standard Kodak daylight loading No. 122 roll film. The disk carrying the exposure numbers is set to number 1 at the beginning of each new film roll by pressing the reset button.

To index the film, the rack is pushed down against the rack stop. This forward motion of the rack turns the drive pinion and thus turns the film driving roll. The ratchet mechanism on the pinion drive shaft prevents the film from unwinding on the return stroke of the indexing rack. As the film is wound on the film driving roll, the diameter of the roll naturally increases and therefore requires fewer revolutions with each successive index. In order to advance the film the $3^3/_4$ inches required for the 3-inch oscillograms, and proper spacing, the number of revolutions is controlled by the length of rack travel for each index. This rack travel is regulated by the stepped rack stop. This rack stop is moved one step per index by the pawl on the end of the film rack.

Typical cards taken with the multi-element oscillograph are shown in figures 25 and 26.

Figure 25 is an oscillogram of three pressure records taken simultaneously on a four-cycle gasoline engine. From top to bottom, the records show pressures measured in the exhaust pipe, intake manifold, and combustion chamber respectively. The combustion chamber-pressure record was taken with a low-pressure indicator developed for use in the combustion chamber.

A comparison between the cards taken with a General Motors Research Laboratory condenser-type indicator and a General Motors Research carbon-stack indicator is shown in figure 26. These cards were taken simultaneously at approximately the same position in the intake manifold of a four-cycle single-cylinder engine.

A pictorial diagram of a complete indicator installation is shown in figure 27.

Indicator Calibration

Various methods have been developed for calibrating a single-card indicator. These methods, in general, can be classified as follows:

1. Static calibration, which consists in applying a known steady pressure to the diaphragm of the indicator and recording the oscillograph deflection.
2. Dynamic calibration, which consists of applying a known dynamic pressure to the indicator diaphragm with a compressor or rotating valve, and recording the oscillograph deflection.
3. Calibration in the engine under firing conditions by a supplementary instrument to indicate a point in the pressure cycle corresponding to a known balancing pressure.

The disadvantage of the first two methods of calibrating is chiefly their failure to simulate actual engine conditions in regard to temperature. After calibrating in a suitable device, the indicator must be

Figure 32

transferred to the engine. This transfer may introduce another source of error in the calibration because of the probability that the forces on the indicator frame in the calibrator will not be duplicated when the indicator is sealed in the engine.

For calibrating under engine firing conditions, two types of balanced pressure indicators are suitable: (1) the balanced valve and (2) the balanced diaphragm. After considering the characteristics of these two indicators, the balanced diaphragm was chosen as the most suitable.

Balanced diaphragm indicators, in general, can be divided into two groups, namely, high- and low-pressure types.

All balanced diaphragm indicators are similar to, or modifications of, the indicator developed by the Bureau of Standards.

Figure 28 is an assembly cutaway of a high-pressure balanced-diaphragm indicator designed and built by General Motors Research Laboratories to include water cooling, small turning radius and improved seat and contact structure. The diaphragm of the high-pressure indicator must be heavy enough (0.002–0.007 inch) to withstand the pressure encountered in the combustion chamber of an engine. The pressure necessary to move the diaphragm away from the contact (one to three pounds) usually is small compared with cylinder pressures. For use in manifolds of engines where maximum pressures are one to ten pounds, it has been necessary to build indicators with extremely thin diaphragms (0.0005 inch) in order to decrease the differential pressure necessary to open the contact. A specially designed indicator had to be built for use with these thin diaphragms to prevent wrinkling, buckling, twisting, sticking, and diaphragm rupture, see figure 29.

The seat and diaphragm are assembled as a separate unit before installation in the indicator frame, see figure 29. The thin diaphragm 0.0005 inch is placed between the two clamping rings and held in place by six counter-sunk screws as shown in figure 30. This method of clamping prevents twisting of the diaphragm. The diaphragm is then stretched by screwing the bottom seat in place. The upper seat is then screwed against the top of the diaphragm, forming a seal where the bottom stretching seat makes contact with the diaphragm (see figure 30). Both the upper and lower seats contain many small holes for passage of the gas to the diaphragm.

The clearance between the upper and lower seats is very small (0.002 inch) in order to limit the maximum movement of the diaphragm.

In figure 29, the seat assembly is shown mounted in the indicator frame. After assembly, the insulated adjustable electrode is lowered until it makes contact with the diaphragm. Caution should be exercised when making this adjustment to avoid rupture of the thin diaphragm. The recommended method of adjustment is to close a high-impedance electrical circuit (such as a neon light and resistor) when the insulated electrode contacts the diaphragm. If this adjustment is properly made, the pressure necessary to break the electrical circuit should not exceed two inches of water.

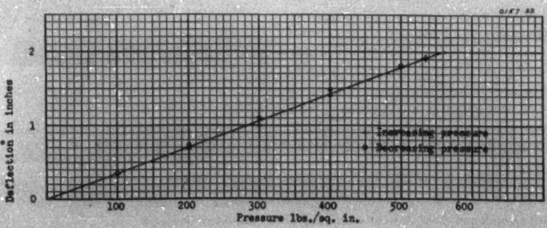
The multielement oscillograph can be used for recording individually and simultaneously the single-card indicator diagrams as well as breaks produced by the balanced-diaphragm indicators. This method eliminates the distortion produced on the single-card indicator diagram by the superimposed calibration marks.

The electrical circuit used to indicate the "make" and "break" of the balanced diaphragm is shown in figure 31.

The neon light is used to give a visual indication of the balanced-diaphragm operation. The adjustable resistor (*R*) is used to limit the current in the circuit and may be adjusted to any desired value.

Figure 32 shows two of a series of calibrated indicator cards taken with the multielement oscillograph. The method of calibration is as follows: referring to card number 6, in figure 32, the balanced diaphragm makes contact at (*A*) when

Figure 33



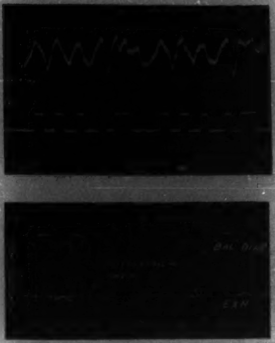


Figure 34

the engine pressure exceeds the known balancing pressure (200 pounds per square inch) above the diaphragm. This contact remains closed until the engine pressure drops below the balancing pressure. This is shown at point *B* on card number 6.

Since the time axes of both diagrams are identical, points *A* and *B* may be perpendicularly projected to the points A_1 and B_1 on the indicator diagrams.

The vertical displacement of points A_1 and B_1 is measured from the atmospheric datum line. This displacement is produced by a known balancing pressure and thus gives two points on a calibration curve. From a series of cards it is possible to obtain a complete calibration curve, see figure 33. This calibration may be superimposed on a single card (card number 7, figure 32).

Some apparent hysteresis between the increasing and decreasing pressure calibration can be seen in figures 32 and 33. The cause of this apparent hysteresis is not definitely known. Studies are being made on this problem.

The peak pressure of 535 pounds per square inch shown on card number 7, figure 32, is obtained from the calibration curve, figure 33.

Figure 34 shows two low-pressure calibrated cards taken in the manifold of an engine. These cards clearly show the ability of the balanced diaphragm to follow low-pressure waves.

Figure 35 is a calibrated high-pressure combustion-chamber record taken on an Allison aircraft engine running at 2,600 rpm.

Other Applications of Condenser-Plate Indicator Equipment

The principle of the condenser-plate indicator and its associated electrical equipment is not limited to pressure measurements. The technique and equipment developed for measuring pressure can be applied to studying the amplitude and wave form of small deflections of moving bodies. A few of the applications in the automotive field are listed below:

Measurement of instantaneous air flow
Measurement of stress and strain
Measurement of flywheel deflection
Measurement of cylinder head and block deflection
Obtaining valve-lift diagrams
Use in propeller-shaft balancing machines

This type of instrumentation might have the following possible uses in other engineering fields:

(1). Measurement or indication of unbalance in high-speed rotating machinery

(2). Vibration measurement

(3). Pressure surges in oil-circuit breakers

(4). Measurement of water hammer and other hydraulic surges

(5). Gun pressures

The Geometry of Arc Interruption

E. W. BOEHNE
MEMBER AIEE

Synopsis: It is the purpose of this paper to present a rigorous analysis and description of the phenomenon which takes place in an interrupting device during the interval between the parting of the contacts and the current zero at which interruption takes place. It is to be shown that the events which take place during the arcing period prior to interruption play an important part in setting the stage for the drama of circuit interruption. This analysis has a counterpart in the phenomenon which takes place immediately following interruption; namely, circuit recovery characteristics. The knowledge of this latter phenomenon has played a dynamic role during the past ten years. With its aid, oil circuit breaker designs have advanced to the point where their excellent performance has set the high present-day standards of reliable circuit interruption.[2,3] The knowledge of recovery rates[4,5] laid the foundation for the displacement principle;[6] namely, oil velocity multiplied by the oil dielectric (impulse) strength is equal to the maximum permissible rate of rise of recovery voltage.

The stage today, however, is being set for interruptions with devices which employ air as the medium of interruption and insulation.[7,8] New roles are being created. Recovery voltage, although just as important, is being assigned an easier part. It is to be shown by means of a straightforward application of the principles of circuit theory, presented in simple graphical form, that the phenomenon which takes place during the arcing period can be so controlled as to reduce the initial recovery voltage, and its rate of rise, to a comparatively small value. It will be demonstrated that the arc in a particular type of air circuit breaker can be put to work to change the phase angle of the circuit from the 90-degree lagging current, associated with normal short circuits, to a leading phase angle at the current zero of arc interruption. The interval necessary to accomplish this conversion is less than one cycle. Exact arc energy relations are presented which define the watt-hours liberated in terms of the kilovolt-amperes interrupted. Although subject to a strict mathematical proof, the graphical counterpart has been chosen for presentation in which an area method of arc current determination is developed. The graphical method, with its various area relationships and energy criteria, offers opportunities of developing methods of rapid visual oscillograph interpretation. The treatment should prove of interest not only to the user of interrupting devices, but also to students of applied circuit theory.

Mental Springboards

No. 1. The Rheostat Breaker

As an entirely different approach to the problem of circuit interruption, consider a single-phase a-c breaker replaced by a rheostat, figure 1. To represent the closed breaker, all the resistance is turned out. With the development of a short circuit, let it be assumed that the rheostat handle is turned to insert more and more resistance until ultimately the resistance becomes so high as to meet the definition of an insulator. It is agreed that the current will have been interrupted. The voltage across the rheostat will have changed from zero to the full circuit voltage. The evolution of the changes which take place throughout this circuit as resistance is gradually inserted are shown in the circle diagram of figure 1. The understanding of these relationships forms a stepping stone toward the appreciation of the events which take place as resistance is inserted *rapidly* into an otherwise inductive circuit.

RESISTANCE R, IN PER UNIT OF CIRCUIT REACTIVE OHMS, X$_L$

Figure 1. Circle-diagram analysis of the changes which take place as resistance is inserted gradually in an otherwise inductive circuit

Note that wattage reaches its maximum value when the resistance is equal to the ohmic reactance of the circuit. At this point the current is reduced to only 70.7 per cent of its maximum value

The salient features of figure 1 are: (1) The short-circuit current, I_{sc}, prior to rheostat operation lags the generated voltage, E, by 90 degrees. This is the normal zero power-factor relation encountered in short-circuit studies. (2) The rheostat resistance, shown in the linear scale, is expressed in per unit of the inductive ohms, x_L, which in turn limited the short-circuit current, I_{sc}. (3) A straight line drawn from the point P to the desired rheostat resistance determines the direction or phase angle of the resulting current. (4) The current magnitude is defined by the semicircle designated as "the locus of the current vector, as resistance is inserted." (5) The product of this current and the corresponding resistance defines the voltage, E_R, which appears across the rheostat. This voltage is always in phase with the current and its magnitude is defined by the semicircle designated as "the locus of rheostat voltage." (6) The product of rheostat current, I, and rheostat voltage, E_R, is the rheostat wattage, W. This product is shown as the curve designated as "the locus of rheostat watts." It is of particular significance that this wattage reaches its maximum value when the rheostat resistance in ohms is equal to the ohmic value of the external reactance. (7) The reactance voltage is always at right angles to the rheostat voltage. The locus of the reactance voltage, E_L, is the upper semicircle. Note that the vector sum of the reactance and resistance voltage is at all times equal to the generated voltage, E. (8) Time, and hence energy relations, do not enter this diagram. All values presented are rms or as would be indicated by the voltmeter and ammeter.

The rheostat, like a breaker, can only introduce a resistance in the circuit.

Paper 41-61, recommended by the AIEE committee on protective devices, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 28, 1940; made available for preprinting December 17, 1940.

E. W. Boehne is research engineer for the General Electric Company, Philadelphia, Pa.

This paper is based on a thesis submitted in partial fulfillment of the requirements for the degree of Electrical Engineer, The Agricultural and Mechanical College of Texas, April 1940.

The author wishes to acknowledge the assistance of students N. Burgess, Jr., R. S. Edwards, J. S. Quill, and I. H. Van Horn, Jr., in the graphical computation and preparation of the figures of this paper. The helpful suggestions of C. Concordia of the central station engineering department of the General Electric Company are also acknowledged.

1. For all numbered references, see list at end of paper.

Hence, many of the above relations have an exact counterpart in the interrupting device. The above explains, for example, why the arc current and arc voltage of a breaker are always in phase, requiring the arc voltage to reverse sign with the arc current. It is of particular importance to note that as resistance is added to the zero power-factor circuit, the current is reduced, and at the same time, its angle with respect to the voltage is decreased. Moreover, as these changes take place, the wattage increases and becomes a maximum at the 45-degree angle, as mentioned above. Note that at this point the current is reduced to only 70.7 per cent of its maximum short-circuit value. As the resistance is increased above the value of x_L, the current, phase angle, reactance voltage, and wattage all decrease. These changes all favor more desirable interrupting conditions. Figure 1 teaches that as resistance is added gradually to the inductive circuit the current and voltage approach unity power factor or zero phase-angle relations only as the resistance approaches infinity and the current approaches zero. It will be demonstrated later that desirable leading phase-angle conditions are created when resistance is added rapidly.

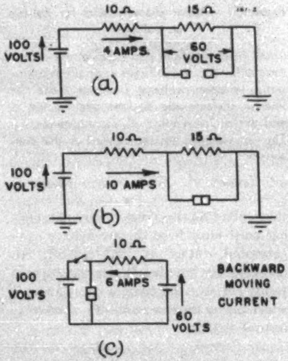

Figure 2. Simple battery circuits which demonstrate that the voltage drop across any element may be used to produce a backward-moving current (figure 2c), which when subtracted from the forward-moving current (figure 2b), produces the net current (figure 2a)

No. 2. Superposition

Consider the simple battery circuit of figure 2*a*. Here a 100-volt battery delivers 4 amperes to a 10-ohm and 15-ohm resistor in series. The voltage drop across the 10-ohm resistor is minus 40 volts, while the voltage drop across the 15-ohm resistor is minus 60 volts. It is of value to compute the current of this circuit in a slightly different manner. For example, let the 15-ohm resistor be shorted out by the primary contacts as shown in figure 2*b*. The resulting current is then ten amperes. Now short the battery out and compute the back moving current produced by the above 60-volt drop, shown in figure 2*c*, as a 60-volt battery. This produces a backward moving current of six amperes. The net current flowing is hence ten minus six, or four amperes.

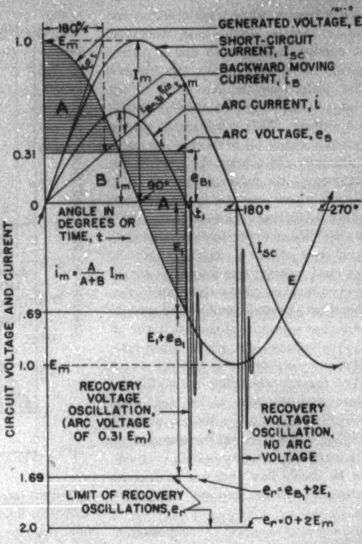

Figure 3. Keynote diagram showing the geometry of arc-current determination

This figure presents a comparison between the associated arc currents, *i*, and the initial recovery voltage, e_r, resulting from two arc voltages; (1) zero value and (2) a flat-top arc voltage of 31 per cent of the generated voltage crest. The entire diagram can be constructed from the generated voltage with the aid of a straight edge and planimeter

This simple procedure embodies perfectly sound principles of superposition. Too little use is made of the advantages it offers. In addition to being particularly useful in facilitating the computation of more difficult circuits than the above, its application will be found of value as an aid in visualizing the accompanying phenomena. It is of particular value when the voltage being studied appears across a circuit parameter which is nonlinear such as the arc of a tube or circuit breaker. As applied to circuit interrupting devices, it states that the voltage produced by the arc of an interrupting device can be used to compute a backward-moving current, which, when subtracted from the short-circuit current that would have existed had not the breaker been tripped, will result in the true arc or circuit current. The voltage across the breaker may vary in any manner whatsoever without altering the validity of the solution. The parameters of the circuit external to the breaker, however, must remain linear. The only parameter external to the breaker for the majority of heavy fault currents is the inductive reactance of the circuit as shown in figure 1. When the arc voltage, and hence the arc current are available, their product determines arc wattage and their ratio arc resistance. Hence, from a design standpoint it becomes possible to investigate various types or families of arc voltage characteristics with the aim of determining which characteristic is most desirable in an interrupting device. Such an examination will now be made.

Determination of Arc Current, Arc Energy, and Maximum Initial Recovery Voltage

Case I. Rectangular or Flat-Top Arc Voltages

With the primary contacts of the breaker closed, the symmetrical short-circuit current, I_{sc}, lags the generated voltage, *E*, by 90 degrees (figure 3). The current, I_{sc}, reaches its peak as the voltage, *E*, passes through the zero value of breaker voltage. This same current would continue to flow in the arc of an opened breaker which developed no arc voltage. Hence, in this case, when the arc current reaches zero and is interrupted, the voltage across the breaker must spring from the zero value of arc voltage to the then crest value of generated voltage. This condition is closely approximated in oil breakers. In negotiating this sudden jump the inherent capacitance of the external circuit comes into action and gives rise to the recovery voltage oscillation. This oscillation permits the voltage to rise to double the generated crest voltage as shown in figure 3. This crest voltage, which appears across the open breaker, will be designated as e_r throughout this study and will be used in addition as a measure of the rate of rise of recovery voltage, over which it has control in any given circuit.

Any breaker which has the ability to reduce the value of e_r to less than this maximum value of $2E_m$ will enjoy a corresponding increase in interrupting ability or in its factors of safety or both. It will now be shown how this can be accomplished through the medium of arc voltage.

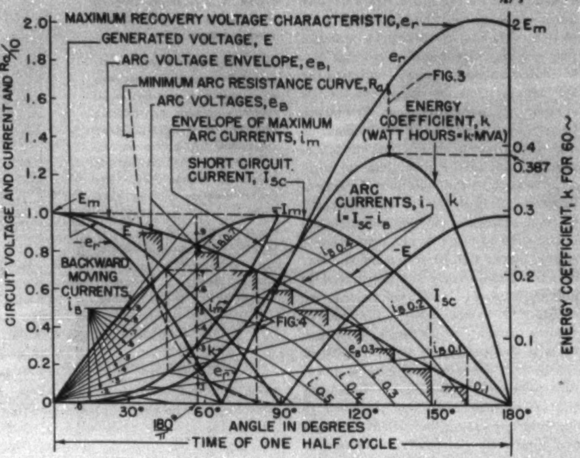

Figure 5. Master characteristics for flat-top arc voltages

These relations show the effect of the magnitude of flat-top arc voltages upon the resulting initial recovery voltage peak, e_r; the arc energy characteristic k; the arc current i; and the minimum value of arc resistance R_a. The arc voltages are introduced as the symmetrical short-circuit current passes through zero

Consider the contacts of the breaker of figure 3 to part as the short-circuit current passes through zero as indicated. Assume that the arc voltage, e_B, which develops throughout the passage of the next loop of current is 31 per cent of the crest of the generated voltage. As previously pointed out this voltage acts to produce a backward-moving current, i_B. For the case of a constant or flat-top arc voltage of $0.31E_m$, acting alone on an inductance L, the current produced rises linearly and at a rate of $0.31E_mt/L$, which is 31 per cent of the initial rate of rise of the short-circuit current, I_{sc}, following a current zero. These relations are all shown in figure 3. Since this current is opposing the original short-circuit current, the true net arc current is expressed in figure 3 as the difference between I_{sc} and i_B. This new current is plotted as i. This current reaches its crest when the arc voltage e_B is equal to the generated voltage. This follows from Kirchhoff's law since at this moment the voltage across the inductance L must be zero. The arc current i arrives at a current zero when the backward-moving current i_B is equal to the forward-moving short-circuit current I_{sc}. This current zero occurs about 45 degrees earlier because of the action of the arc voltage. If interruption takes place at this current zero the voltage must jump from the arc voltage e_B to generated voltage at that instant. In making this transfer it has the opportunity of overshooting a like amount which places the new value of e_r at $1.69E_m$ instead of $2E_m$.

Arc Energy. Arc wattage is the product of arc current i and the arc voltage e_B. The latter, in this case, being a constant makes the true wattage proportional to the arc current. Arc energy in watt-seconds is equal to the area under the wattage-time curve. In this case the energy in watt-seconds is equal to the area under the current curve multiplied by $0.31E_m$. This case gives the maximum energy for the flat-top arc voltages under the conditions of figure 3. Had the arc voltage been higher or lower than $0.31E_m$ the energy would have been less. In this case the arc energy converted to watt-hours gives:

watt-hours = 0.387 MVA (60~)

where MVA = megavolt-amperes interrupted.* Hence the interruption of

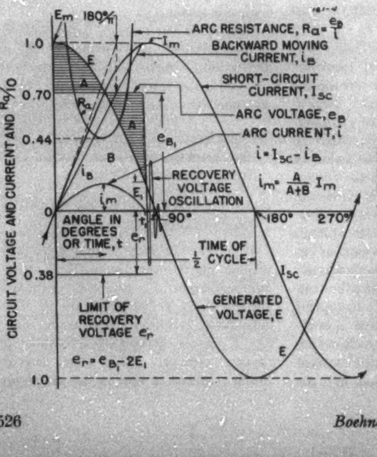

Figure 4. Leading current interruption produced by a flat-top arc voltage of 70 per cent of the generated voltage crest

An oscillogram of this desirable type of interruption is exhibited in figure 12a. The cathode-ray oscillogram of figure 12b shows that the type of recovery oscillation sketched here is so highly damped that the voltage limit, e_r, was never obtained

---

*100,000 kva = 100 MVA.

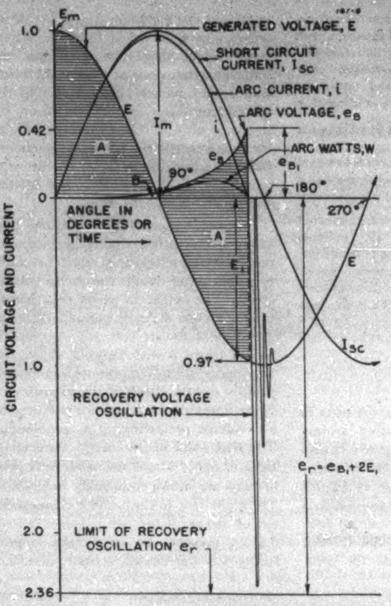

Figure 6. An arc voltage characteristic, e_B, which produces the same arc energy as the case of figure 4

Note the high initial recovery voltage, e_r, of $2.36E_m$ as compared with the corresponding value of $0.38\,E_m$ for figure 4

25,000 amperes at 4,000 volts single phase would release only 39 watt-hours at this maximum energy value. In general, the watt-hours released during any interval will be expressed by the relation:

$$\text{watt-hours} = k\cdot \text{MVA} \tag{1}$$

The relationship of k for the above family of flat-top arc voltages is shown in figure 5.

Graphical Solution. The entire solution of figure 3 can be made with a planimeter and slide rule once the arc voltage characteristic is established. The maximum value of the arc current i is given by the ratio of areas:

$$i_m = \frac{A}{A+B} I_m \tag{2}$$

This relation follows from the fact that the area represented by

$$\int_0^{t}(E-e_B)dt \text{ must equal } L\cdot i=\psi \tag{3}$$

The current at any time t' can hence be determined from the above by measuring that portion of the area A up to t'; namely A'. The current at that instant is then:

$$i' = \frac{A'}{A+B} I_m \tag{4}$$

It follows that when the area between E and e_B is again A, following arc current peak, the current must again arrive at zero. This satisfies the flux linkages of the inductance L, the momentum of the magnetic circuit.

The planimeter solution is particularly suitable when the arc voltage varies in any irregular manner. After computing the wattage curve the planimeter becomes useful again in computing the energies. The majority of the relations developed for this presentation were computed graphically. It is interesting to note that in the case of the flat-top arc voltage of figure 3, it can be proved that maximum energy occurred when the area under the backward-moving current triangle omt_1 is half the area under the short-circuit current I_{sc} up to the instant of arc current zero at t_1.

Leading Phase-Angle Interruptions. It has been shown that the flat-top arc voltage of $0.31E_m$ reduces the initial peak of recovery voltage from $2E_m$ to $1.69E_m$. As higher flat-top arc voltages are assumed this initial recovery peak shrinks rapidly. Figure 4 shows a graphical solution of the case where the arc voltage is $0.70E_m$. Here the backward-moving current i_B intersects the forward-moving short-circuit current I_{sc} at such an early point that the difference gives rise to an arc current i which arrives at an interrupting current zero nine degrees ahead

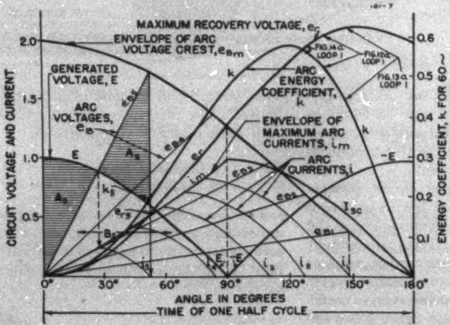

Figure 7. Master characteristics showing the development of arc current, i; initial recovery-voltage peak, e_r; and arc-energy characteristic, k; as a result of linearly rising arc voltages

The arc voltages are introduced as the symmetrical short-circuit current passes through zero

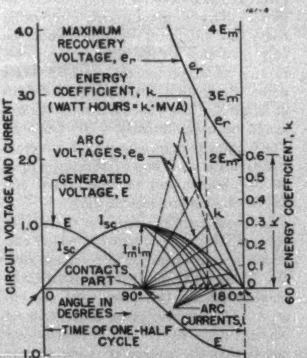

Figure 8. Master characteristics produced by linearly rising arc voltages introduced as the symmetrical zero-power-factor short-circuit current passes through its maximum value. Compare with figure 7

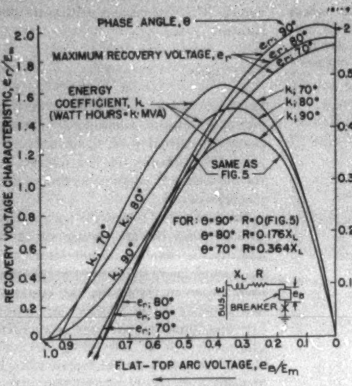

Figure 9. Characteristics showing the effect of external circuit resistance upon the maximum initial recovery-voltage characteristic, e_r, and upon the energy coefficient, k

Note that as the phase angle is decreased due to external resistance the resulting value of e_r is reduced, while the value of k is increased

These relations were obtained with flat-top arc voltages applied as the symmetrical short-circuit current passes through zero. Direct comparison should be made with figure 5

of the voltage zero. Hence at interruption the voltage drops from $0.70E_m$ arc voltage to the generated voltage which, at that instant, is $0.16E_m$. This gives the voltage oscillation an opportunity to reach an initial peak, e_r, of only $0.38E_m$. The damping of the voltage oscillations, however, in modern interrupting devices which are capable of accomplishing this phase-angle change, is so great that the recovery from arc voltage to generator voltage takes place with little or no oscillation. Figure 12*b* shows a cathode-ray oscillogram of the nature of such a transition following the leading phase-angle interruption presented in figure 12*a*.

Arc resistance, the ratio of e_B/i, is plotted on figure 4. The minimum resistance reached was only 4.4 times the external reactive ohms which limited the initial short-circuit current. In actual ohms this minimum resistance would be only 0.70 ohm in the case of the interruption of 25,000 amperes at 4,000 volts under the leading phase-angle conditions of figure 4. The rms current in the arc would be approximately 4,000 amperes. The k value to determine watt-hours from equation 1 is 0.147 hence liberating a total of 14.7 watt-hours for the above 100 MVA, single-phase interruption.

It is interesting to contrast the case of figure 4 with that of figure 6 which embodies a case where the arc voltage rises late in the cycle as shown. Both cases liberate exactly the same total arc energy. The leading phase-angle case of figure 4 gives rise to the extremely low initial recovery voltage of $0.38E_m$ while the corresponding value for the almost zero power-factor interruption of figure 6 is $2.36E_m$. These relations correspondingly define the relative recovery rates associated with the two interruptions. The low arc current of figure 4 results in less metal vaporization during arcing. The shorter arcing time of figure 4 is also in favor of less wear and deterioration.

Characteristic Curves. Just as figures 3 and 4 show the resulting arc currents and recovery voltages as a result of flat-top arc voltages of $0.31E_m$ and $0.70E_m$ respectively, so figure 5 shows the complete story for all flat-top arc voltages. The lines of figure 4 can be found in figure 5 since the latter is constructed by assuming arc voltages of 10 per cent, 20 per cent, ... 70 per cent . . . . . 90 per cent, of the maximum circuit voltage. The corresponding arc currents are shown plotted only for that portion following the arc current peaks. This arrangement permits the locus of arc current peaks to be drawn as shown. The maximum recovery voltage e_r and the energy coefficient k of figure 3 and figure 4 become points on the complete e_r and k characteristic curve shown in figure 5. These latter values should be read from the horizontal time scale at the instant which they occur; namely, coincident with the arc current zero. The minimum arc resistance curve is shown with respect to the time at which the particular minimum value occurred; namely, at the arc current crest corresponding to the flat-top voltage under consideration.

An examination of figure 5 shows that as arc voltage is introduced the maximum recovery characteristic e_r starts to climb to values above double the circuit voltage crest. The height to which this characteristic climbs depends particularly upon the shape of the arc voltage. A comparison of figure 6 with figure 5 shows the flat-top arc voltage to produce a minimum peak of e_r. A study of the geometry of figure 6 reveals the reason for this type of arc voltage producing an e_r of $2.36E_m$. The peak value of the energy characteristic k of figure 5 and the associated phenomena are shown completely in figure 3. The rapid drop in the e_r and k characteristic of figure 5 for arc voltages above $0.31E_m$ presents an attractive opportunity for the circuit breaker designer. The oscillographic exhibits in this paper present a new interrupter which functions with these desirable characteristics.

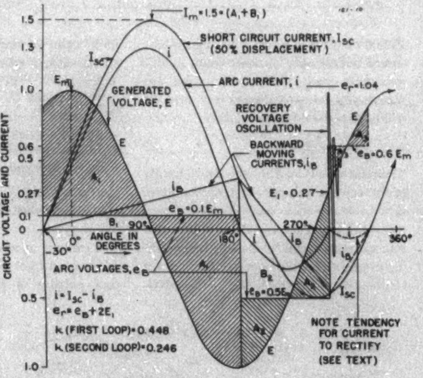

Figure 10. Graphical solution of a multi-half-cycle interruption for a zero-power-factor short-circuit current having 50 per cent displacement

Flat-top arc voltages of $0.1E_m$ and $-0.5E_m$ are applied respectively for the first and second loops. A third current loop is made impossible by the current rectification produced by any flat-top arc voltage greater than plus $0.27E_m$

CASE II. LINEARLY RISING ARC-VOLTAGE CHARACTERISTICS

The foregoing treatment of the flat-top arc voltage as presented in figures 3, 4, and 5 is applicable to any type of arc voltage. When the arc voltage rises linearly, as

$$e_B = K_e t \qquad (5)$$

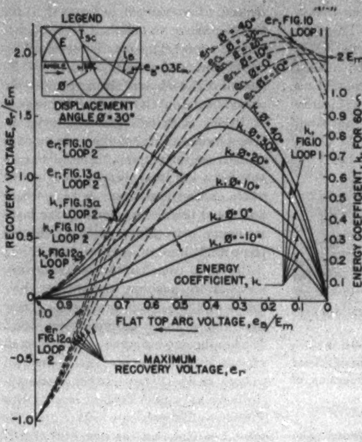

Figure 11. Characteristics of maximum initial recovery voltage, e_r, and energy coefficient, k, for flat-top arc voltages introduced at current zeros which occur at the indicated angles ahead of the circuit voltage crests

These characteristics are particularly useful in compounding the analysis of multi-half-cycle arcs

the backward-moving current is more complex, following the equation

$$i_B=\frac{K_0}{2\cdot L}t^2 \tag{6}$$

For this reason the graphical solution (area method) is often more rapid. The wattage curve is more complex inasmuch as neither the arc current nor the arc voltage is constant. The energy computation, however, is just the same, namely

$$W=\int_0^t e_B\cdot i\cdot dt \tag{7}$$

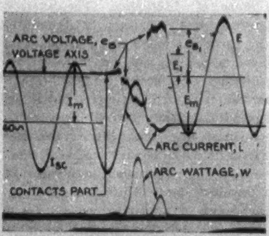

Figure 12a. Oscillogram showing how the Magne-Blast breaker shifts the current zero from 90 degrees behind the voltage to 21 degrees ahead of the voltage in a time of less than one cycle

Current: 13,800 amperes. Voltage: 3,920. The analysis of the first loop can be obtained as indicated on figure 7. This produces a phase displacement of 41 degrees. The second loop can then be analyzed as shown on figure 11. The bottom trace shows arc watts. Measured energies for the two loops give 29.3 watt-hours and 9.8 watt-hours, respectively. Calculated values give 28.4 and 10.2 watt-hours, respectively

The graphical computation of energies is recommended for speed.

Figure 7 presents the complete evolution of the linearly rising arc voltage starting from current zero of a symmetrical short circuit. This case shows slightly different k and e_r characteristics than the flat-top wave. Inspection will show the flat-top wave to be superior to the linearly rising arc voltage.

Case III. Contact Parting at Other Than Current Zero

Figure 8 presents the characteristics which arise as a result of linearly increasing arc voltages which develop as the contacts are parted at the current crest. The graphical solution was made, as previously outlined, keeping in mind that the areas must be balanced at the end of each current zero, as shown in figure 6. This case is important as it is useful in compounding the complete story of the multi-half-cycle interruptions to be studied in the oscillographic cases to be presented.

Case IV. Effects of External Resistance

Short-circuit current studies are usually made neglecting the effects of circuit resistance. For this reason the values of current calculated are usually higher than normally experienced. Under actual conditions, however, fault currents can occur which instead of being 90 degrees behind the generated voltage are only 80 degrees or 70 degrees behind due to the effects of the circuit resistance and the effective resistance of the fault itself. Figure 9 presents the k and e_r characteristics resulting from flat-top arc voltages produced as the interrupting device parts its contacts at a current zero. In this case, the arc voltage produces a backward-moving current, i_B, which is limited by a resistance R in addition to the inductance L. It will be observed that there is beneficial decrease in the values of e_r over those shown in figure 5, the corresponding case without external resistance. This decrease in e_r has been proved oscillographically and shows the presence of external resistance to be helpful. This has been found to be true in spite of the corresponding increase of the energy coefficient k as shown in figure 9.

The values of figure 9 are plotted with respect to the magnitude of the flat-top arc voltage and in this respect differs from figures 5 and 7. The e_r and k characteristics of figure 5 are replotted on figure 9 to the new scale. These are shown as the 90-degree phase-angle curves and are hence available for direct comparison with the corresponding characteristics for the 80-degree and 70-degree phase-angle curves. For all curves the current has been kept at 100 per cent; that is, in spite of the addition of resistance the current has not been reduced. In order to execute the area method in this case it will be necessary to add to the area A the corresponding area under the voltage which appears across the external resistance. For this reason this case is often more readily solved by computing the backward-moving current and subtracting same from the short-circuit current to obtain the true arc current.

Case V. Arc Currents of More Than One-Half Cycle

The principles outlined above are applicable to arcs of more than one-half cycle. Following the current zero of one loop of arc current, the arc voltage reverses sign with the current. The new

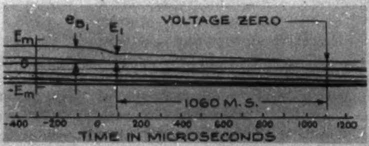

Figure 12b. Cathode-ray oscillogram showing the transition from arc voltage to circuit voltage accompanying the interruption shown in figure 12a. Note the absence of voltage oscillation

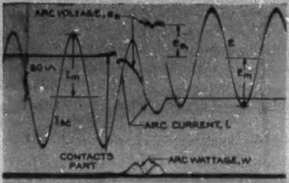

Figure 13a. Oscillogram showing how the Magne-Blast breaker shifts the interrupting current zero 90 degrees to coincide with the generated voltage zero

Current: 5,270 amperes. Voltage: 3,900. The analysis of this oscillogram is indicated on figure 7 (first loop) and figure 11 (second loop). The bottom trace shows arc watts. Measured energies for the two loops give 9.25 and 8.22 watt-hours respectively, while calculated values give 9.45 and 7.95 watt-hours respectively

arc voltage then creates a new backward-moving current which acts as outlined above. Figure 10 shows a graphical solution, which in addition assumes a short-circuit current which is not symmetrical. Unsymmetrical currents are produced in totally reactive circuits when the short-circuit current is initiated at any instant at which the voltage is not at its maximum value. The case of figure 10 shows a 50% displacement at contact parting. The initial arc voltage is $0.1E_m$ of the flat-top variety which reduces the arc current crest from $1.5I_m$ to $1.30I_m$. When the areas balance the current arrives at zero producing an e_r of almost $2.1E_m$; $k=0.448$. The arc current continues in a new environment where the arc voltage is now $-0.5E_m$. This produces a backward-moving current whose slope is now

$$i_B = \frac{-0.5E_m}{L}t \qquad (8)$$

This current is shown in figure 10 and starts where the old backward-moving current of the previous loop left off. The resulting second loop of current peaks at $0.3\ I_m$ and when the net voltage areas balance again, a new current zero arrives. Here the new e_r is only $1.04E_m$ following a k of only 0.246. Here interruption takes place. It is interesting to note that if the current attempted to reverse and produce a flat-top arc voltage above $0.27E_m$, then the resulting current would not have reversed, but would have rectified as shown in figure 10 for an arc voltage of $0.60E_m$. However, if the current cannot reverse, neither can the arc voltage. These conditions, hence, define an impossible state of affairs. Tests show that when this condition tends to exist that interruption invariably occurs. This leads to a new and interesting criterion for interruption which for complete analysis must not neglect the inherent capacitance of the external circuit. The graphical analysis presented in figure 10 reveals a technique which may be applied to any multi-half-cycle interruption of zero power-factor short-circuit current. The oscillograms presented in figures 12, 13, and 14 may be studied with the above in mind.

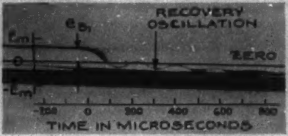

Figure 13b. Cathode-ray oscillogram showing the transition from arc voltage to generated voltage associated with the interruption of figure 13a

Multi-half-cycle arcs are also associated with the interruption of symmetrical short-circuit current. Their analysis follows the pattern as developed in figure 10. The initial loop of arc current, which has been modified by its arc voltage, will have shifted the phase angle of the circuit at current zero an amount depending upon the magnitude and shape of the arc voltage. See figures 5, 7, and 10. This shift sets up the phase angle at which the second loop of current must start. An inspection of the area method of arc current determination shows that it is of advantage to keep the initial loop of arc voltage low if a second loop is to be experienced. For example, in figure 10, if the first loop of arc voltage had been $0.05E_m$, instead of $0.1E_m$, then the second loop would have ended with an e_r of $0.78E_m$ instead of $1.04E_m$ and the k value for the second loop would have been 0.144 instead of 0.246. This fact points directly to design trends which have been mastered in modern air interrupters,[8] namely to provide for a low resistance arcing chamber where an arc in air may develop length and speed prior to its entering the high-resistance path where zero and leading phase-angle interruptions are created.

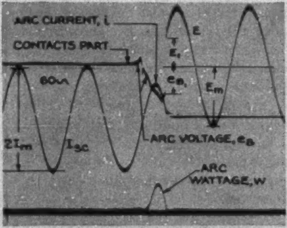

Figure 14a. Oscillogram showing how the Magne-Blast breaker interrupts 20,600 amperes at 3,820 volts, single phase, with a single loop of arc current

The analysis of this interruption is indicated on figure 7. The bottom trace of arc watts measures 44.6 watt-hours while the calculated value is 43.3 watt-hours

Hence, to complete the data necessary for accurate analysis, the characteristic curves of figure 11 are presented. These show the e_r and k characteristics which develop for flat-top waves which start at various angles ahead of the generated voltage peaks. These displacement angles may have been created in a variety of ways by the previous loop of arc voltage. The fact that the new loop of current is dependent only upon the phase angle and not upon how that phase angle was obtained, makes the data of figure 11 extremely useful in compiling the analysis of design or oscillographic data. This is particularly true for the oscillographic cases to be considered here since the second loop of arc voltage is almost invariably of the desirable flat-top variety. A comparison of the data in figure 11 with the equivalent phase-angle changes brought about by the presence of external resistance, figure 9, will be found of interest.

Scope of Application. The analysis presented in this paper is not limited to any particular interrupter. It has been found useful not only in analyzing the performance and design features of certain arc chutes of air interrupters, but it has found its application to oil interrupters, contactors, fuses, and lightning arresters. The examples to be presented here, however, are unique inasmuch as they exhibit a degree of performance unequaled by any device of similar rating.

The method also applies to other studies which do not involve the problem of interruption. For example, the decre-

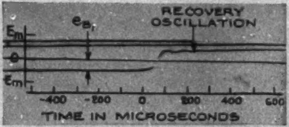

Figure 14b. Cathode-ray oscillogram showing the transition from arc voltage to circuit voltage accompanying the interruption shown in figure 14a

ment factors for the attenuation of unsymmetrical short-circuit currents due to the resistance of an arcing ground may be developed with considerable speed by the above application of multi-half-cycle arc phenomena. Also the problem of the magnitude and shape combinations of the voltage across an electric arc furnace may be studied with the aim of determining which combination gives the maximum heat output in an electric furnace. The above method is particularly adaptable to this problem during the burning-in period where steady-state conditions are not maintained.

Application to Oil Circuit Breakers. It is beyond the scope of this paper to discuss thoroughly the application of this treatment to oil circuit-breaker performance. A review of the above, however, with respect to the typical oscillograms of oil circuit-breaker performance shows that inherently this well-established interrupter does not and should not develop a high arc voltage. The oil device functions best when its arc gap, following interruption, is insulated with clean, cool oil. The development of arc voltage, as demonstrated by old plain break breakers, produced energy (k) and recovery voltage (e_r) characteristics approaching those shown to the right of figures 7 and 8 for the first half cycle of arc. This energy unquestionably blew the oil away from the arc and did not permit the oil, unaided, to reinsulate the arc gap rapidly enough to cope with the arrival of the first peak of recovery voltage (e_r). The arc, on continuing, produced more energy on the next half cycle due to the phase-angle shift created on the first half cycle as indicated by figure 11. This repeated the blowing of oil away from the contacts at the same time heating the oil and the pocketed gas. The result was that interruption could not take place until the contacts became so far apart that re-establishment was impossible. This gave rise to the old long arcing breakers.

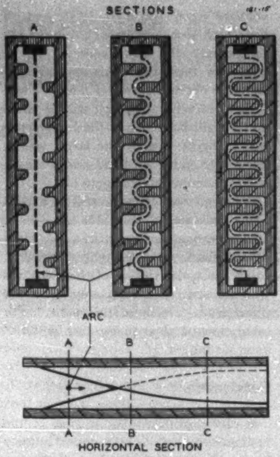

Figure 15. Arc-chute construction of the Magne-Blast air circuit breaker

This figure is repeated here for the convenience of the reader in appreciating how the high arc voltages of figures 12, 13, and 14 were obtained

With the introduction of the oil blast principle[9] the little energy developed during the first half cycle of arc was put to work to blast clean fresh oil across the other contact. These conditions lead to an early interruption with the minimum of developed energy. Arc lengths and arc voltages are hence held to a minimum. The impulse breaker[10], which creates its oil blast by means of an auxiliary piston, creates interruptions at the first current zero following contact separation with extremely low arc voltages. This breaker[4] follows the displacement principle as mentioned in the synopsis of this paper.

Magne-Blast Performance. The Magne-Blast air circuit breaker was described before the Institute in 1939[8] and its extension to larger interrupting capacities is announced with this paper. The 1939 paper described a 150,000-kva, 5,000-volt breaker which produced phase-angle changes from 40 to 50 degrees with accompanying reductions in rates of rise of recovery voltage. The present announcement of a 7,500-volt, 250,000-kva breaker has been made possible by close study of test and design criteria. The new device produces phase-angle changes which exceed 90 degrees and hence gives rise to leading phase-angle interruptions with recovery voltage characteristics of such a nature as to require that new definitions be established to describe them. The operation of the new and larger breaker is the same as previously described[8] with the addition of an improved means of extinguishing the light currents rapidly. Table I presents a typical series of three-phase tests, at various voltages, showing interrupting times well below an over-all time of eight cycles for all currents from transforme magnetizing value to well above the interrupting rating. Particular attention should be paid to the short arcing times for the higher current interruptions. The advantages of this feature are obvious from the text of this paper.

The oscillograms presented exhibit the single-phase performance at approximately 4,000 volts. In addition to the normal oscillographic records of arc voltage and arc current, a new oscillograph record is shown; namely, arc watts. This trace makes available on inspection the relative energies in adjacent loops of arc current. The oscillograms presented were chosen more to present the characteristics of performance rather than demonstrate high interrupting capacity. The latter is adequately presented in table I.

Figure 12*a* shows the interruption of 13,800 amperes, single phase, at 3,920 volts. Neglecting the minor positive kick of arc voltage, the first major arc voltage can be approximated from the triangular

Table I. Interrupting Tests on 1,200-Ampere Indoor-Type Magne-Blast Air Circuit Breaker

Interrupting Rating—250,000 Kva, Three Phase

	Current Amperes in Max. Phase				
Test Volts	Max. Loop Peak Value	Initial in Arc RMS	Kva Three Phase	Arcing Time—Cycles	Cycles From Trip Impulse to Interruption
7,250	12.0	8.4	Transformer	0.6	4.7

7,250	175	121	currents	1.9	6.0
7,250	870	330		1.9	6.0
7,500	1,690	830	10,800	2.1	6.5
7,500	4,200	2,000	26,000	1.5	6.0
7,500	12,500	5,300	71,000	0.9	5.8
7,500	23,000	9,500	124,000	0.9	5.8
7,500	37,000	14,500	188,000	0.8	5.0
7,500	45,000	21,000	270,000	0.8	5.3
6,600	1,260	640	7,300	2.5	6.7
6,600	2,700	1,400	16,000	1.9	6.3
6,600	12,000	5,200	59,000	1.1	5.3
6,600	34,000	13,600	155,000	0.8	5.3
6,600	58,000	23,000	260,000	0.5	4.8
6,600	72,000	26,000	300,000	0.5	4.8
4,200	70,000	34,000	250,000	0.9	4.4
4,200	97,000	38,000	280,000	0.6	4.0
2,300	77,000	45,000	180,000	0.6	4.9

case of figure 7. This point of figure 12*a* is indicated on figure 7 and gives an e_r voltage of 11,380, a k of 0.528, and produces a phase displacement of 41 degrees. Using this latter displacement as a starting point for the second loop of current we turn to figure 11. Approximating the arc voltage of the second loop as $0.84E_m$, the final loop ends with an e_r of 555, a k of 0.190, and a phase displacement of 21 degrees. This shows a multi-half-cycle case which results in a leading phase-angle interruption as shown. A comparison with figure 4 is instructive. The measured area under the wattage loops shown on figure 12*a* produce 29.3 and 9.8 watt-hours, while the insertion of the above estimated k values in equation 1 produce 28.4 and 10.2 watt-hours respectively.

The maximum e_r value of 555 volts at interruption never occurred due to the high damping of the recovery oscillation, a condition created by the breaker.[8] Figure 12*b* presents the cathode-ray oscillogram of the transition from arc voltage to generated voltage at interruption. The transition is accompanied by no oscillation. The generated voltage then floats through zero some 1,060 microseconds later as shown. Since not even the recovery voltage changed sign at current zero, it follows by the area method that current continuation is impossible. The inherent recovery rate of the circuit under the conditions of figure 12 is 1,100 volts per microsecond. The measured recovery rise for figure 12*b* is less than 1.0 volt per microsecond. The ability of the Magne-Blast breaker to create and maintain arc voltages of this type lies in the novel construction[8] of the new interleaving arc chute, shown in figure 15. This arc chute is designed with one particular objective in mind; namely, to create and maintain high arc voltages.

The analysis of the oscillograms presented in figures 13 and 14 may be carried out as in the case of figure 12. The captions describe the measured watt-hours and other necessary information for the recalculation of the oscillograms from the curves presented in this paper. It is of particular interest to study the wattage trace of figure 13 with respect to the nature of the arc currents and arc voltages upon which it is dependent. Here both loops of current produced approximately the same energy. The k points for these two loops are indicated on the k characteristics of figures 7 and 11, respectively. The first will be found on the right-hand side of the k characteristic of figure 7 while the latter will be found over on the left-hand side of the 30-degree characteristic of figure 11.

Although the cases presented exhibit single-phase performance, the three-phase analysis is just as straightforward. It is beyond the scope of this paper, however, to present a description of their analysis which is merely a compounding of the principles set forth in this paper. For tabulation of three-phase test performance, see table I.

Conclusions

A straightforward application of the fundamentals of electric circuit theory has been made to the analysis of the pre-interrupting phenomena of circuit interrupters. It has been shown that the arc voltage developed by any interrupting device may be considered, quantitatively as well as visually, to produce a backward-moving component of current. This current when subtracted from the initial forward-moving current produces the true resulting arc current. Arc wattages, arc energies, arc resistances, and phase angles are then immediately available. The dependence of these latter quantities in any given circuit upon the arc voltage has made possible the presentation of these relations for various families of arc voltage characteristics. Other curves are presented which enable the fundamental criteria of circuit interruption to be obtained for a wide variety of performance characteristics. Consideration has been given to symmetrical and unsymmetrical short circuits, the effects of external resistance, arcs of more than one half cycle, and other practical cases.

Specific application is made to the unique performance characteristics of the Magne-Blast air circuit breaker.[8] It is shown how this device, through the medium of high arc voltage, transforms a 90-degree lagging short-circuit current to a leading current at interruption with less than one cycle of arcing. Initial recovery voltages are expressed showing enormous reductions. Exact energy relations are presented which express the watt-hours liberated in terms of the kilovolt-amperes of the interruption. The study of the unique Magne-Blast breaker performance characteristics first aided the development of this treatment and in turn has been aided in its extension to higher interrupting ratings by the use of this treatment as a design tool.

Although applied specifically to the Magne-Blast breaker, the principles presented are applicable to oil breakers, contactors, fuses, and other interrupters, both a-c and d-c. It also finds its application to problems apart from interrupting devices, particularly when the voltage across a nonlinear parameter is to be studied. The treatment should prove of interest not only to the user of interrupting devices, but also to students of applied circuit theory.

An Experimental Investigation of Subharmonic Currents

JOHN D. McCRUMM
ASSOCIATE AIEE

THIS investigation of the series circuit shown in figure 1, consisting of resistance, capacitance, and nonlinear inductance, was undertaken with a view of determining the behavior of the subharmonic current which may result when a sine-wave voltage of fundamental frequency is applied. The magnetization characteristic of the inductor is given in figure 2, and all results, therefore, are associated with this one particular inductor. All values of resistance are ohmic values.

The behavior of this circuit in a state of subharmonic oscillation is not well known. The increasing use of series capacitors to overcome the inductive reactance drop of transmission systems has brought attention to the inadequate knowledge of the occasionally abnormal behavior of these networks. This application of capacitors usually brings about improved and automatic voltage regulation; however, unusual transient and sustained overcurrent phenomena often result in the system for certain operating conditions. Instead of normal sinusoidal currents there will be currents greatly increased in magnitude, and having a variety of wave shapes of most unusual form. Since series capacitors are nearly always associated with one or more transformers, this type of network may be reduced to a simple series arrangement of capacitance, resistance, and an iron-core inductor whose inductance may not be considered constant. It is the simplest circuit known to exhibit the peculiarities under investigation.

The difficulties encountered in any attempt to analyze mathematically the behavior of this circuit arise from the fact that the inductance is a function of the current. This results in a differential equation which is nonlinear, and therefore not solvable by ordinary methods. It is also necessary to make certain assumptions which might not be justified were all the basic facts known.

Previous investigators resorted to the use of a mechanical differential analyzer to solve certain of these equations.[1,2,3] Idealizing assumptions were made neglecting resistance or any form of dissipation, and neglecting hysteresis and eddy current effects. Fallou[4] has suggested the use of this circuit as a frequency divider. Investigation by others[5–15] was restricted to what has been commonly called "ferroresonance" with only a brief mention of a possible subharmonic response. The location on the voltage-current diagram of subharmonic currents, particularly with reference to the two states of ferroresonance, has been uncertain. The voltage-current diagram is the plot of the rms value of impressed voltage versus the rms value of the current. There is also a confused difference of opinion regarding the effect of initial conditions on the ultimate behavior of the response. Travis and Weygandt[1] give analytical substantiation to the hypothesis that initial conditions, such as switching angle (the point on the voltage wave at which the switch is closed) are important in determining the subharmonic response of the circuit at a time considerably after any switching transient would have died out. Weber's discussion of this paper concludes that switching angle has nothing to do with the ultimate response of current and states further that, "Otherwise any practical use of the relay circuits based upon the critical features of the ferroresonant element would be incomprehensible." Obviously, confusion exists, since the state of subharmonic oscillation, and the state of ferroresonance are entirely different phenomena. To clear up these misunderstandings, and to establish a more substantial basis for further investigation has been an aim of this paper.

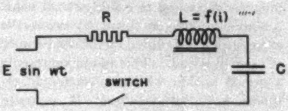

Figure 1. Circuit investigated

The experimental work described includes the following: an account of the regions on the voltage-current diagram capable of supporting subharmonic oscillations, the relation of these regions to the phenomenon of ferroresonance, oscillographic records of wave shape, and the effect of initial conditions on subharmonic response.

The Region of Subharmonic Response on the Voltage-Current Diagram

The definition of a subharmonic response is appropriate. When a sine wave of voltage (unvarying amplitude and frequency) is impressed on this series circuit there can exist currents in which the lowest frequency component is a submultiple of the applied frequency. These currents are called *subharmonics* and the circuit is said to be in a state of subharmonic oscillation. A state of oscillation of order s exists when the resulting current has a period s times as long as the period of the impressed voltage; that is, the wave form repeats every s cycles of the impressed voltage. The component of frequency $1/s$ times fundamental frequency is not necessarily, however, the largest component.

With proper values of circuit parameters, impressed voltage, and initial conditions, a subharmonic current of the most common type, which is of order three, can be obtained by the simple process of closing the switch. This third order current may fall into one of three classifications: sustained and stable; sustained but unstable, that is, erratic or

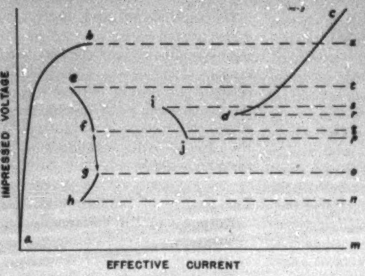

Figure 3. Possible current responses of the series circuit

Section *a-b*, low-current curve

Sections *e-f* and *g-h*, subharmonic of order three

Section *i-j*, subharmonic of order two

Section *c-d*, high current of ferroresonance

"jittery" and having no definite order; and transient. Once the oscillations are initiated, the variation of the rms value of current as the rms value of the applied voltage is changed is described by reference to the curves *e-f* and *g-h* of figure 3. Subharmonic oscillations cannot be obtained if the voltage is greater than at point *e* or lower than at point *h*. Suppose the voltage to be in the range *q-t*. This makes possible the sustained response on curve *e-f*. Having initiated the subharmonic oscillations, increasing the applied voltage within this range so as to approach the point *e* causes the current to decrease, and at point *e*, the oscillations suddenly cease and the current falls back on curve *a-b*, the low-current curve. (This low-current curve is essentially a portion of the magnetizing curve of the inductor.) If, on the other hand, the voltage be decreased so as to approach point *f* the subharmonic current instead of remaining stable until *f* is reached becomes erratic upon nearing this point. When *f* is reached, the oscillations abruptly cease as occurs at point *e*, and the current takes a value corresponding to the curve *a-b*.

Operation on the curve *g-h* is similar to that on *f-e*, except that the unstable or erratic response occurs at the high voltage end *g* of the range. If the voltage is adjusted to a value between *q* and *o* and the switch closed, subharmonic currents will often result, but they die out after a few cycles of oscillation.

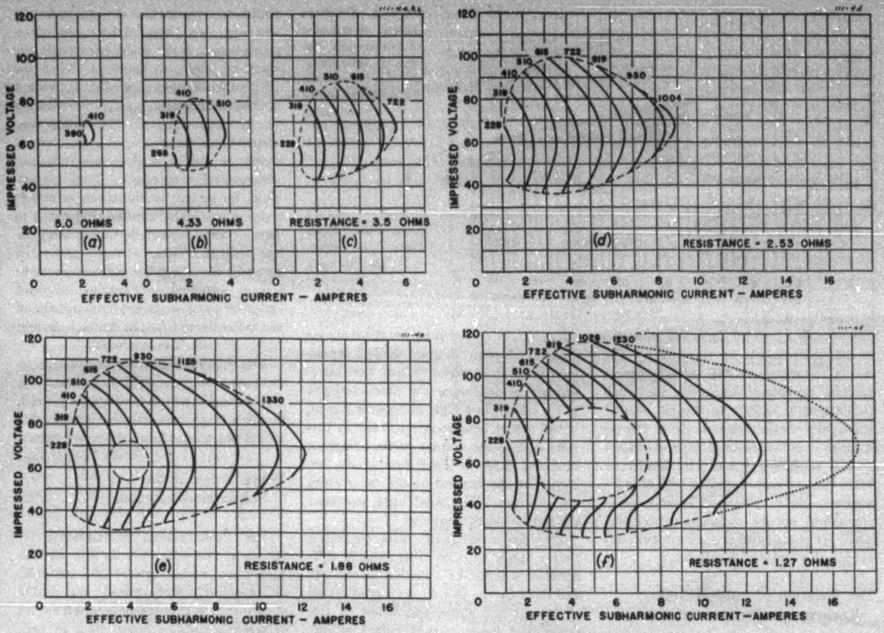
Changing one or both of the parameters, resistance and capacitance brings about marked changes in the response of the circuit. If the capacitance be reduced but resistance left unchanged, then for a given voltage, the subharmonic current will be less. The upper and lower limits of response (*e* and *h*) will be brought closer together, and the gap between *f* and *g* will tend to close. For a capacitance sufficiently small, the two sections *e-f* and *g-h* merge forming a continuous curve. There is a certain lower critical value of capacitance below which, no subharmonic currents can exist. Increasing the capacitance produces much the same effect except that the resulting current is larger. The gap *f-g* will close, and there is a certain upper critical value of capacitance above which no subharmonic currents can exist.

Let us now determine the effect of varying the resistance while keeping the other parameters unchanged. Starting with a high value of resistance it is impossible to obtain any subharmonic response whatsoever. As far as subharmonics go, the region of the voltage-current diagram presents an unbroken expanse of what will be likened to an open sea. The resistance must be decreased to a fairly small value (about five ohms in this case) before the expanse of sea is ruffled by the appearance of a small island. This island represents a region within which subharmonic response may be obtained. It is quite small because of the limited range of capacitance which will support subharmonic currents for this value of resistance, but for any capacitance permitting these oscillations, the resulting curve of current versus impressed voltage is continuous. This small island is shown in figure 4*a*. Continuing the reduction of resistance causes the island to grow larger and the range of capacitance which will support the oscillations to increase. Figures 4*b*, 4*c*, and 4*d* show this clearly.

From figures 4*a* to 4*d* the resistance has been decreased a definite amount. Further reduction brings about an important modification within the island region. No longer is each curve continuous for every value of capacitance. A lake now appears in the island, and the region within this lake is incapable of supporting sustained subharmonic currents; any subharmonic response which can be initiated corresponding to this region rapidly dies out. It is, therefore, a region of transient response. This lake may be fairly small as shown in figure 4*e*, but reducing the resistance enlarges the size of this inner region as well as the island itself, until at a comparatively low value, both the island and the region of transient response are very large. The dotted boundary at the right of figures 4*f* and 4*g* was extrapolated and is only approximate. Lack of sufficient capacitance prevented carrying the experiments above those values indicated.

The boundaries of this lake are precisely determined at the left or lower capacitance side. The upper and lower boundaries are reasonably well defined; the right side boundary is rather indefinite. A region of erratic operation borders this region of transient response in much the same way as a marsh may exist around the shores of a lake; this is shown in figure 5. This erratic current, though unstable in behavior, possesses some sort of stabilizing factor, as it will usually continue to exist with its typical though unpredictable wave form for an indefinite period. The right side of the lake of transient response merges gradually into the marsh of erratic response, however, and a sizable region exists here where the current is more than merely "jittery." Its oscillations are violent and fitful, some cycles having peaks four or five times greater than corresponding peaks of other cycles. Subharmonic oscillations may exist in this state for several minutes and then after a violent oscillation, die out; or, they may go on indefinitely.

Extremely valuable would be information enabling one to adjust the parameters in such a way as to assure a sustained subharmonic response, or to definitely prevent it. The curves of figure 6 show the range of the two parameters, resistance and capacitance, for which subharmonic oscillations may exist either in sustained form, or in transient form, provided that the impressed voltage is correct and the initial conditions favorable. Above, or outside of curve *A*, there can be no subharmonic response, for this region corresponds to operation on the open sea. The region contained between the two curves *A* and *B* is synonymous to operation within the island but outside of any lake of transient behavior that might exist, and therefore to sustained response. Any point below curve *B* corresponds to operation within the region of transient response. The final trace of these curves as the resistance approaches zero is not known, but they probably intersect the abscissa and do not become asymptotic to it. If this is not the case then the results of any analytical investigation which neglects the effect of resist-



ance will prove difficult to substantiate experimentally, and at best would be liable to considerable question. It might be well to mention that many peculiarities not recorded herein were experimentally observed when the resistance was very low.

The foregoing discussion has been concerned with the behavior of the most common type of response, which is of order three. Occasionally a subharmonic current will obtain which is not of this order. Those of order nine, six, and two have been observed experimentally, and others no doubt exist.

Subharmonic currents which repeat every six, or nine, cycles of the impressed voltage, and most probably all others of higher order, exist only within the marshy region of erratic operation. The response in this region is not always, then, what might be termed erratic, and if the rigid requirements of the initial conditions are met the response may be of some definite order higher than three. Oscillograms of such currents are shown in figures 12*a* and 12*b*. It should be stated that the relation of voltage versus current for this oscillation is narrowly confined within the erratic region and is essentially the same as would result if the order were three. Unless an oscillograph were available there would be no way of knowing that the response was not of third order. The conditions permitting such a response are extremely limited and usually a slight variation of impressed voltage will cause the order to change or make the current erratic thus having no definite order.

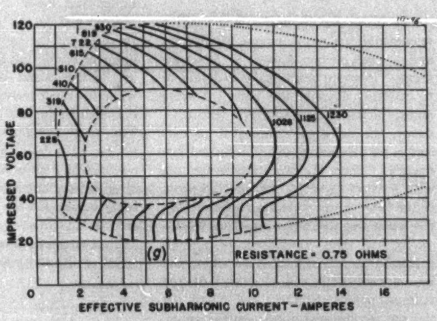


Figure 4. Regions of subharmonic currents of order three

Figures of individual curves refer to capacitance in microfarads. The dotted boundary of *f* and *g* was extrapolated

Subharmonic oscillations of order two behave in much the same way as those of order three. However, the oscillations of order two result in currents roughly twice as great in rms value as corresponding currents of third order, and when plotted on the voltage-current diagram reveal a region quite apart from any regions previously mentioned. Referring to figure 3, a typical characteristic curve is shown as *i-j*. An actual plot of effective current of order two against impressed voltage is disclosed in figure 7. At best these second order oscillations are fickle; requirements of voltage, switching angle, etc, to initiate them are very rigid, as well as the requirements of the circuit parameters in order that their existence be maintained. This response may be abtained only for a very limited range of resistance and capacitance

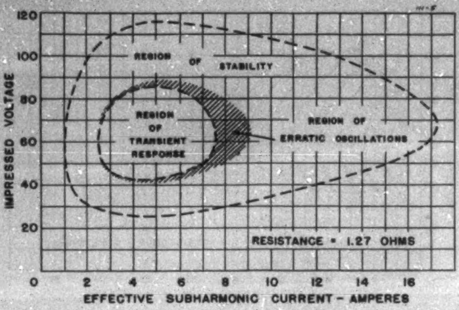

Figure 5. The three regions of response of subharmonic currents of order three, showing in particular the region of erratic oscillation

(about from 1.5 to 2.0 ohms and from 400 to 530 microfarads in this case). The size of the region on the voltage-current diagram capable of supporting sustained oscillations of order two become smaller and finally diminishes entirely as the resistance is increased or decreased from a certain optimum value. It should be noted that no corresponding lake of transient response is evidenced, as such operation could not be obtained experimentally. It is doubtful if such a region exists for this order of oscillation.

The Relation of Subharmonic Response to Ferroresonance

The series circuit under investigation may exhibit both subharmonic oscillations and a phenomenon known as *ferroresonance.* It would be advisable to define, or to carefully describe the latter. During an exhibition of the response of ferroresonance, the principal component of current is very definitely of fundamental frequency. There are two states associated with ferroresonance. The first is known as the low-current state, and is essentially the lower magnetizing current of the inductor. If the impressed voltage is gradually increased from a low value, the low-current curve will be traced on the voltage-current diagram, and when the voltage reaches the upper critical value, the current will suddenly increase. The circuit is now operating in the second, or high-current state and a further increase of voltage merely increases the current correspondingly. If now, the voltage be decreased to somewhat less than the first critical value, the lower critical value of voltage will be reached and the current will collapse suddenly to a value synonymous with the low-current state. In figure 3, the curve *a-b* is the low-current curve and the high-current curve is given by *d-c.*

For a given inductor, the effect of resistance and capacitance on these curves is easily shown. A great deal of experimental investigation[5–15] has been performed to determine the characteristics of the circuit in a state of ferroresonance; it will suffice here merely to refer to this work and to the voltage-current diagram of figure 8 for an exhibition of the behavior of the current as the parameters are changed. The solid lines represent the ferroresonant response.

Previous investigators have suggested that a region capable of supporting subharmonics would be bounded on the left and right by the two ferroresonant states of current and above and below by the upper and lower critical values of impressed voltage. The actual condition is revealed on the plots of figure 8. The outer heavy dotted line forms the boundary of the island of stable oscillation, while the inner heavy dotted line, if present, bounds the lake of transient response. The nonlinear characteristic of the inductor is the essential feature of the series circuit which gives rise to both conditions of operation, but beyond that, the underlying causes for the behavior of the resulting current are probably as different as the two phenomena themselves.

All of the foregoing discussion reveals that for a certain value of impressed voltage, one, two, three, or four current responses may result if the parameters are suitable. Refer to figure 3. When the voltage is adjusted to a value between *n* and *o*, two response possibilities exist for the given parameters. The current may respond on curve *a-b*, the low-current curve, or may be subharmonic in nature and respond on curve *g-h*. Thus it is possible, for certain combinations of circuit parameters including the inductor, to find a condition such that when the voltage is set to a value between *r* and *s*, the response may be a low-current on curve *a-b*, a sustained subharmonic of third order on *e-f*, a sustained subharmonic of second order on *i-j*, or be the high-current of ferroresonance on curve *c-d*.

Although no response other than those indicated was obtained experimentally, Travis[3] indicates that others may exist. In such case, there may be innumerable modes of response for given circuit values.

Wave Form in the Subharmonic Region

The instantaneous subharmonic response of the series circuit may be sustained and stable, erratic and unstable, or transient. A sustained and stable steady state is that response which has an apparently definite order, such as two, three, six, or nine. An erratic response is usually sustained, although it may suddenly die out for no apparent reason, and has no definite order. A transient response is that which occurs immediately after closing the switch, persists for a few cycles, and then dies out. Oscillograms of the wave form of the sustained and stable steady state, and the erratic response are shown.

The change in wave form of one cycle of a sustained third order current as an excursion is made along a characteristic curve on the voltage-current diagram is

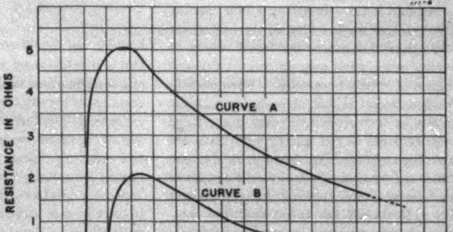

Figure 6. Limiting values of resistance and capacitance for third-order oscillations

Above and to the left of curve *A*, no response; between *A* and *B*, sustained and stable oscillations; below curve *B*, region of transient response shown by figure 9. These were taken on a cathode-ray oscillograph with constant amplification. Note how greatly the wave form changes in the vicinity of the lake region of transient response, figures *c* and *d*, and *e* and *f*. The last record, 9*i*, was taken after the upper limit of the curve had been passed and the current had collapsed to three cycles of what is essentially the magnetizing current of the inductor.

A somewhat similar excursion is given in figure 10,* and figure 11.

Current wave forms of order nine and six are shown in figure 12. In the first record note that the current wave repeats every nine cycles of the impressed voltage, and that while nine fundamental cycles are required for one period of subharmonic current, each third of the period is similar to one typical current cycle for order three. Thus, three similar but different third order cycles can be considered grouped to form one cycle, or period, of order nine. Similarly for order six.

An oscillation of order two is shown by figures 13 and 15*c*. This response is of unusual interest: it is difficult to initiate and maintain, and is quite different from the response of any other order. A resistance as high as 6,000 ohms when connected across the capacitor materially changes the wave form of this oscillation, or may cause it to die out entirely, indicating how sensitive this response is to circuit changes.

The long oscillogram of figure 14 reveals a current response which is erratic. An oscillation such as this may persist indefinitely and never "settle down" to any regular predictable form or it may last for only a short period, say ten seconds or even a minute or two, and then for no obvious reason suddenly snuff out.

There are four possible sustained current conditions which may be obtained for certain restricted but fixed values of the parameters and the impressed voltage. Oscillograms of these four responses for essentially the same impressed voltage and circuit parameters are exhibited in figure 15. Note particularly that the high current of ferroresonance is not subharmonic in nature.

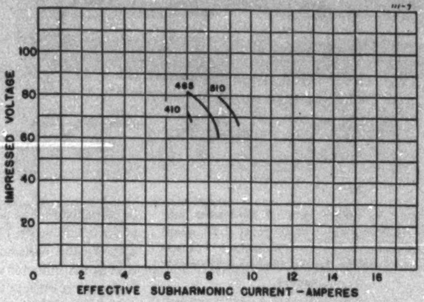

Figure 7. Subharmonic currents of order two; resistance of 1.88 ohms

An examination of the wave forms exhibited leads to two comments. First: if the form of one cycle of a sustained current of third order be taken as a basis, then the form of the currents of orders other than three is comparable and similar to three. Second: at any instant in our circuit maintaining a subharmonic oscillation, there are certain conditions of voltage, charge, and flux linkages, in sign, magnitude, and time rate of change. It would appear then that if all of these conditions identically match at every three cycles of impressed voltage, the current response should then repeat identically thus leading to a sustained third order oscillation. If the matching conditions occur every two cycles, a second order wave results; if it requires nine cycles, then ninth order and so on. If these conditions never match or repeat then a wave form of erratic nature is the result. Thus it seems entirely possible that what might appear to be an erratic response on an ordinary oscillogram is actually a portion of a response of very high order, and an oscillogram of great length would be necessary to detect the order.

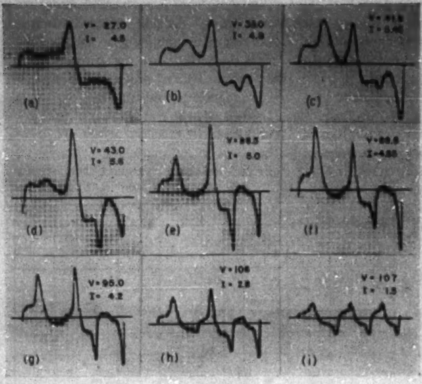

Figure 9. Wave form of third-order subharmonic current, resistance of 1.27 ohms, capacitance of 615 microfarads. V is impressed voltage, I is the effective subharmonic current

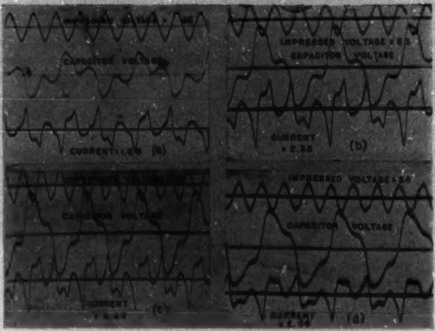

Figure 10. Wave form of third-order subharmonic current, resistance 1.27 ohms, capacitance 319 microfarads

Initiation of Subharmonic Oscillations

There are three factors which act on the circuit initially. These are:

(*a*). Initial flux linkages of the inductor.

(*b*). Initial charge on the capacitor.

(*c*). Manner of applying the impressed voltage.

Assume for the moment that the voltage is applied by suddenly closing the switch. The inductance of the iron-cored reactor is essentially constant until some degree of saturation occurs. Since subharmonics depend for existence on the nonlinearity of the inductor, it is obvious that for any given switching angle, the initial flux linkages and initial charge must be such as to permit the necessary degree of saturation to occur. If the first few cycles of response after closing the switch do not result in the necessary degree of saturation, no subharmonic response will be obtained.

The manner of applying the voltage to the circuit determines whether any subharmonic response at all will result. Experiment proves that in no case is it possible to induce a subharmonic response by impressing the voltage at an unsuitably high or low value, and then gradually bringing the voltage into the range capable of supporting oscillations for the given parameters. This merely results in a high or low current of ferroresonance. To initiate subharmonic oscillations, a shock excitation is required. This must be administered at suitable initial values of switching angle, charge, and flux linkages for the necessary degree of saturation in the inductor which is caused by a high peak of current can be brought about only by a judicious combination of these initial conditions.

A much greater "shock" is necessary to produce oscillations of order two than for the more common type of order three. Occasionally, by repeatedly closing the switch, the circuit may be made to give subharmonics of second order, perhaps once out of fifty closings. However, if the switch is closed and then the inductor momentarily short-circuited, a very high current will result during the short circuit; this operation will very often initiate subharmonics of order two, and can nearly always be counted on to produce the more common variety of order three. Of course, the moment at which the short circuit is removed is certainly comparable in importance to a switching angle, but the high current produced before removing the short circuit allows a wide range of angle consistent to producing the required oscillations. The rarity with which oscillations of order two occur after merely closing the main switch indicates that a rather special combination of initial conditions must exist before such oscillations can be expected.

Subharmonics of order six and nine are indeed rare in occurrence, which must be attributed to the rigid requirements of initial conditions to produce them as well as the requirements for their continued existence.

The effect of initial charge, flux linkage, and switching angle on the wave shape of any third order subharmonic oscillation that may result depends largely on the region of the voltage-current diagram in which the response falls. If the ultimate response is sustained and stable then

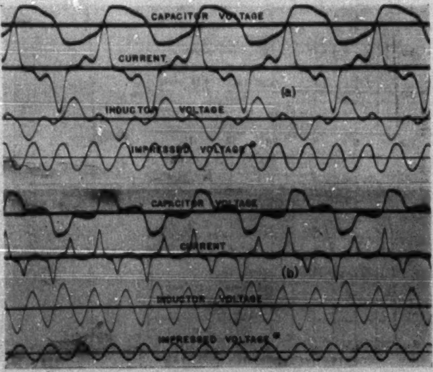

Figure 11. Wave form of third-order subharmonic current, $R=1.27$ ohms

(a)—$C=510$ microfarads, $V=90$ volts, $I=3.6$ amperes

(b)—$C=1{,}026$ microfarads, $V=38$ volts, $I=8.7$ amperes

*Impressed voltage has been sketched in correct phase position

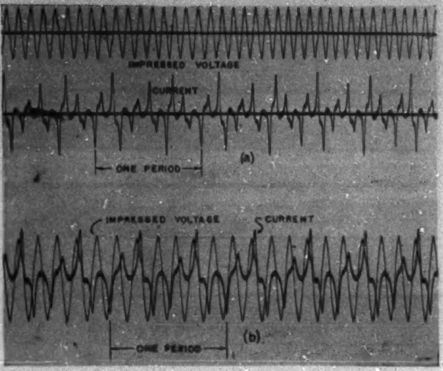

Figure 12

(*a*) — Subharmonic current of order nine. $R=1.88$ ohms, $C=410$ microfarads, $V=73$ volts, $I=3.2$ amperes

(*b*) — Subharmonic current of order six. $R=1.27$ ohms, $C=319$ microfarads, $V=58$ volts, $I=2.45$ amperes

the total response from the instant the switch is closed may be likened to the ordinary linear circuit response which consists of a "switching transient" which shortly dies out leaving the "steady-state" component the wave form of which is independent of initial conditions. If the circuit is adjusted to an oscillation within the lake region, then only a transient subharmonic current will result. However, if the response is erratic a more interesting possibility exits. Travis[3] points out that initial conditions are determining factors in the response for the first excursion of the whole saturation curve, and his region-by-region analysis predicts wave form on what has happened just previously. Thus the instantaneous value of current an hour after closing the switch could be determined by starting with the given initial conditions, and projecting forward to the point desired. That switching angle, for example, could be a factor determining the wave form hours after the switch is closed is incomprehensible to the usual way of thinking, but an examination of the erratic wave of figure 13 certainly suggests this possibility. Certainly, if all initial conditions for this particular oscillogram could be matched, the response for the first few cycles should be repeated and match identically with this one. If at first, why not forever after? In such a case it might be logical to consider the whole response as a transient, even though undamped and lasting for an indefinitely long time, and a steady-state condition, by all the usual definitions, might never be reached.

General Conclusions

Conclusions derived from this investigation may be stated as follows:

1. Subharmonic oscillations are restricted to definite regions on the voltage-current diagram.

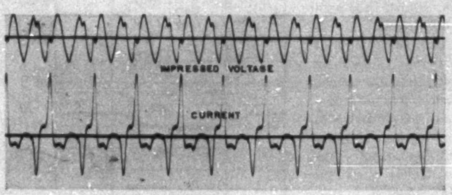

Figure 13. Wave form of subharmonic currents of order two

$R=1.88$ ohms, $C=410$ microfarads, $V=72$ volts, $I=7.1$ amperes

2. The states of ferroresonance and subharmonic oscillation are totally different phenomena unrelated in behavior.

3. For certain suitable but fixed circuit parameters, there may be as many as four different sustained current conditions for the same impressed voltage. They are: low current of ferroresonance, subharmonic current of order three, subharmonic current of order two, and high current of ferroresonance.

4. A "shock" excitation of some form is always necessary in order to initiate subharmonic oscillations.

5. Initial conditions: (1) are important in determining the wave form when the subharmonic response is in the erratic region, (2) are unimportant in determining the wave form of the steady-state sustained response in the region of stable operation; for given parameters, the wave form of current in this region depends only upon the value of impressed voltage.

6. Overcurrent conditions in series capacitor installations may be due to:

(1). Subharmonic oscillations, in which case they may be completely avoided or made to come within the region of transient response by proper selection of circuit parameters.

(2). High current of ferroresonance, in which case the current may be much greater in magnitude than that due to subharmonics, and while it may be reduced by favorable circuit parameters, this phenomenon cannot be wholely avoided except by keeping the voltage down.

Synopsis: Operating records of the Consolidated Edison Company of New York, Inc., revealed the existence of irregular fluctuations in the loads on generating stations and tie feeders. Tests were conducted to determine the response of parts of the system to changes in load, voltage, and frequency. By analyzing the test results to show the relation between these three quantities under various operating conditions, it was possible to establish the origin of the load swings, as well as to determine their magnitude, duration, and recurrence.

Three general types of load swings were observed: small synchronizing power oscillations, short-time swings caused by fluctuating railroad loads, and long-time swings produced by the unco-ordinated adjustments of station loads. These swings are not initiated or sustained by the turbine governors. The synchronizing power oscillations and the short-time swings do not affect system operation, but the long-time swings do affect the loading of the tie feeders and the operation of boiler equipment. It is expected, however, that the greater appreciation of the problem derived from the tests, plus the installation of a common frequency indicator in all stations, will enable the operators to reduce the long-time load swings.

Introduction

The object of the authors whose test results and conclusions are reported in this paper was to secure information on system characteristics which would assist the engineering and operating personnel to meet service requirements adequately and economically.

The tests were conducted at the Hudson Avenue station which carries representative load and is located electrically at the end of the system where it can be isolated easily. Although the steam and electrical parts of a generating station are closely related, the various tests were designed primarily to disclose the electrical response of the system.

Load swings may be defined as deviations from the normal load trend. These have been characterized for this system as:

1. Power oscillations of three to five megawatts with a period of about two seconds in the normal generated load when the station is tied to the system.

2. Short-time load swings with a period of 0.5 to 2.0 minutes and usually not exceeding ten megawatts.

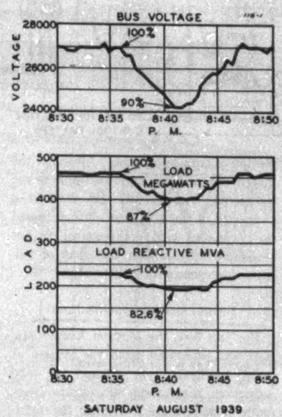

Figure 1. Effect of a reduction in bus voltage on the distributed load

3. Long-time load swings with a period of five minutes or longer and of considerable magnitude.

Importance of Load Swings

On this system the power oscillations and short-time swings do not present any serious problem but the long-time load swings should be kept to a minimum because of the adverse effect upon system economy and operation. Long-time load swings disrupt loading schedules, decrease boiler economy, and add to maintenance costs.

The economy of stoker-fired boilers is reduced by frequent changes in combustion rates which cause irregular fires and reduced furnace efficiency. Thin spots are formed in the fuel bed which reduce combustion efficiency and damage stoker castings with a consequent increase in furnace maintenance. Thicker fuel beds must be maintained to withstand the higher air pressures necessary to pick up sudden load swings. This tends to increase superheater maintenance because of increased secondary combustion.

The rapid variations in steam output decrease momentarily the furnace efficiency of pulverized fuel boilers because of changes in fuel-air ratio.

In boilers having limited steam liberating surface sudden changes in load with attendant change in evaporation rate may cause carry-over. The efficiency of cinder catchers is adversely affected by changes in gas velocities resulting from load swings.

Deviation from economical loading schedules and unnecessary operation over uneconomical valve points decrease turbine efficiency.

Long-time load swings prevent close adherence to system incremental loading schedules and lead the system operator to incorrect anticipation of system load changes. It should be noted that short-time load swings, on the contrary, do not directly affect station economy unless they couple with automatic control equipment in a manner to cause hunting of combustion control apparatus.

Station long-time load swings which are reflected in the tie feeders decrease the effective carrying capacity of these facilities. Additional thermal cycles following these swings accelerate the failure rate of tie feeder cables, reduce tie feeder availability, and increase maintenance costs.

Preliminary Tests

To determine the correct relationship of load to voltage and load to frequency,

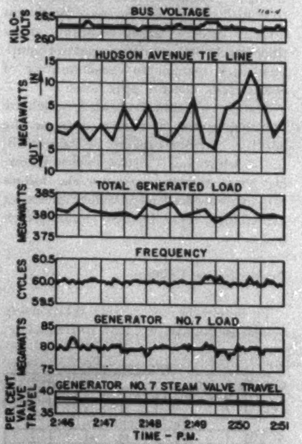

Figure 4. Hudson Avenue load characteristics with the governors automatic and the station tied to the system. Generator 7 is a typical generator. Replot of the oscillograph records with condensed time scale eliminating small power oscillations

preliminary tests were conducted at Hudson Avenue where the information could be obtained on a representative section of connected load. Although the metropolitan New York load reflects the industrial, commercial, and residential character of the area, calculations based on estimated load components do not satisfactorily establish the effect of voltage or frequency on load.

(a). Effect of Voltage on Load

For this test, the Hudson Avenue station was separated from the system at points indicated in figure 14, and induction regulators substations were made nonautomatic. During the lighting peak, the bus voltage was lowered ten per cent in two per cent steps of two minutes each and then gradually increased to normal while the frequency was maintained as nearly constant as possible.

Figure 1 shows that a 10 per cent decrease in voltage resulted in a reduction of 13 per cent in station megawatt demand and 17.4 per cent in reactive megavolt-amperes. The load at the beginning and end of the test was the same. In an emergency requiring temporary reduction of load, the voltage could be lowered within reasonable limits with the consequent rejection of a substantial amount of load without seriously disturbing consumers or endangering stable operation.

(b). Effect of Frequency on Load

The relation of frequency to load within a practical operating range and with voltage held approximately constant is

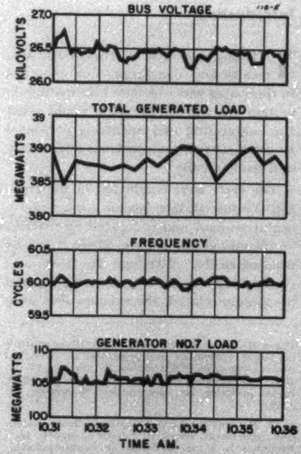

Figure 5. Hudson Avenue load characteristic with the governors automatic and station separated from the system

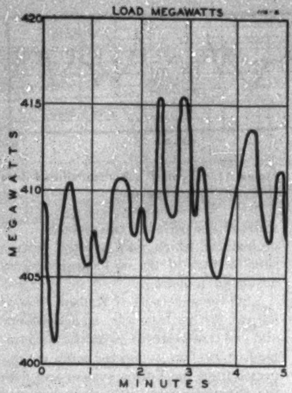

Figure 6. Hudson Avenue load characteristic showing in detail typical short-time load swings with the governors automatic and the station separated from the system

shown in figure 2. A change in frequency of approximately three per cent did not cause any substantial change in load. The load change usually noted when the frequency is altered is the result of the accompanying voltage variation and not the change in frequency. A reduction of frequency in itself does not materially decrease the system load.

Methods of Measurements

To obtain further data on the composite action of the load, generators, governors, automatic frequency control, and tie feeders and their individual contribution to load swings, a group of tests was conducted at the Hudson Avenue generating station.

This required the development of a test procedure to secure continuous and simultaneous records of the following quantities for periods of from 5 to 15 minutes:

1. Total generator load (load fringe)
2. Station frequency
3. Station voltage
4. Load on ties to other stations
5. Steam valve travel of the frequency-regulating turbogenerator

The station recording meters at Hudson Avenue included a totalizing wattmeter, voltmeter, and frequency meter, but these instruments because of their slow chart speed and slow response were considered inadequate for the test and therefore metering circuits which are shown in figure 3, were developed to utilize a nine-element oscillograph with a magazine containing 200 feet of sensitized paper.

(a). Load Fringe Measurement

The important requirement was to record with reasonable precision the fluctuations of about 0.25 to 10 per cent in the total generated load. This was accomplished by a differential current method in which the totalized A-phase current was opposed by a current of constant magnitude and fixed phase displacement. The resultant current was passed through the vibrator circuit of a fin-type single-phase wattmeter element on the oscillograph. The field circuit of this element was energized by a current held at constant magnitude and in phase with the station bus voltage, so that for constant bus voltage the variations in the differential current, and therefore the deflections of the wattmeter element were proportional to the load fringe. The load fringe record was corrected when the bus voltage variations were appreciable. Auxiliary current transformers provided an over-all ratio of 6,000 to 5 amperes for each generator.

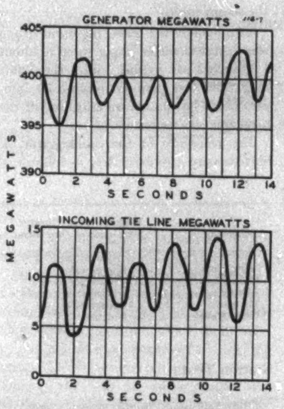

Figure 7. Characteristic power oscillation that exists when Hudson Avenue is tied to the system. Replot of the oscillograph records

The bucking current used to oppose the load current was obtained from a synchronous-synchronous frame shifting motor generator set supplied from the station bus. To hold the magnitude of the bucking current as constant as possible, the fields of the two machines were excited by a station control battery which was isolated for the tests.

To aid in securing stability of the bucking current, an air-core reactor was inserted in the bucking circuit so that the generator could be operated at a voltage near its rated value and still provide the small voltage drop required across the differential circuit whose resistance was of the order of one ohm. Since the inductance of the differential circuit was practically negligible, its impedance drop combined at almost 90 degrees with the much larger drop across the air-core reactor. The use of the air-core reactor had the additional advantage of tending to make the magnitude of the bucking current independent of changes in station frequency. Any changes in the speed and voltage of the bucking generator produced by changes in station frequency were almost entirely offset by proportional changes in the impedance of the air-core reactor.

Before each test run, the proper phase displacement of the bucking current with respect to the load current was secured by a frame adjustment of the motor generator set and the magnitude of the bucking current was adjusted for minimum differential current by varying the field excitation. Following these adjustments the current coils of the indicating instruments in the differential circuit were short-circuited for the duration of the run.

(b). Supplementary Measurements

The frequency record was obtained by passing through an oscillograph vibrator the current in a series resonant circuit energized from the same voltage source as

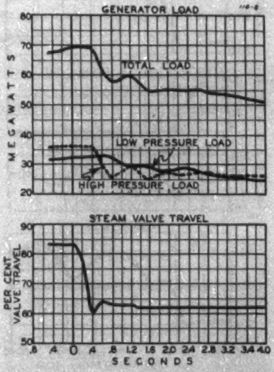

Figure 8. Effect of a sudden change in synchronizing-spring tension on the valve travel and the output of an 80-megawatt cross-compound turbogenerator

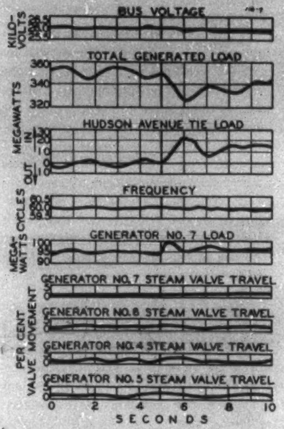

Figure 9. Effect on Hudson Avenue generator and tie-line loads of tripping a generator carrying 20 megawatts. Generator tripped at five seconds on chart. Generator number 7 regulating

the field for the differential wattmeter element used to record load fringe. The circuit was designed for resonance at 62 cycles per second in order to give a practically linear deflection.

A record of the *A* phase-to-neutral bus voltage was obtained by applying the output of a voltage dip amplifier (class *C* amplifier, using a type 53 duotriode) to a sensitive oscillograph vibrator.

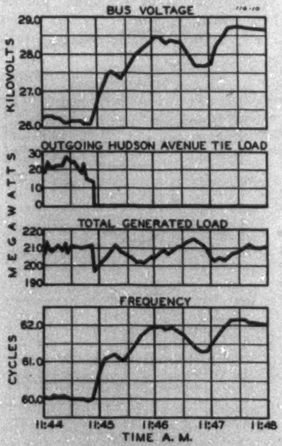

Figure 10. Test results with all governors blocked when an outfeeding tie was tripped. No adjustments made of the field and valve positions

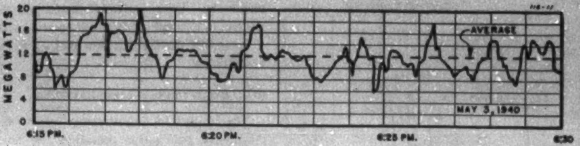

Figure 11. Typical suburban-railroad load demand

The loads on the ties between the Hudson Avenue and East River stations were totalized and recorded on the oscillograph.

To record valve travel, a slide-wire potentiometer was mounted on the turbine frame, with the slider attached to the rod which transmits the movement of the governor's hydraulic amplifier to the steam valves.

Throughout the tests, the oscillograph was operated with a paper speed of about 1.25 inches per second. With the 200-ft magazine, test periods totaling 30 minutes could be run before reloading of the magazine was necessary.

The responses of the oscillograph vibrators were approximately as follows:

Quantity	Magnitude for Vibrator Deflection of One Inch
Load fringe	6 megawatts
Frequency	1 cycle per second
Voltage	2 kilovolts
Tie load	15 megawatts
Valve travel	3 inches

Station Tests

The following tests were made at Hudson Avenue during the flat load period of a weekday except the block governor test which was conducted on Sunday. The weekday demand was about 380 megawatts and the Sunday demand 200 megawatts, and the corresponding spinning capacities were 560 and 430 megawatts respectively. The station voltage was about 26.5 kv. The records of these tests are shown in figures 4 and 5.

The generator load, frequency, and voltage were irregular during both tests but the variations were more pronounced with the station isolated. Short-time load swings were observed with a magnitude of five to ten megawatts and a period of 0.5 to 2.0 minutes. Figure 6 shows in detail the nature of these load swings. When the station was tied to the system there was superimposed upon the generator and tie-line loads an almost continuous power oscillation of about five megawatts with a period of two seconds. The oscillations which were plotted from a short section of the oscillograph record are shown in figure 7.

With the governors at Hudson Avenue normal, further tests were made with one and two ties in service, with the Niagara-Hudson system connected and disconnected from the Edison system and with the automatic frequency control in and out of service at Hudson Avenue. There was no apparent change in the characteristics of the short-time load swings or power oscillations during these tests, thus indicating that these operating arrangements had slight influence on the swings or oscillations.

In order to check whether the governors initiate or sustain these swings or oscillations, a series of tests was conducted in which an exaggerated impulse was introduced at the station in an attempt to start swings or oscillations. The first of these tests was to change suddenly the synchronizing spring tension of the governing mechanism of an 80-megawatt cross-compound turbogenerator. To accomplish this, an auxiliary spring was installed in parallel with the synchronizing spring and arranged with a fusible link so that the tension of the auxiliary spring could be released instan-

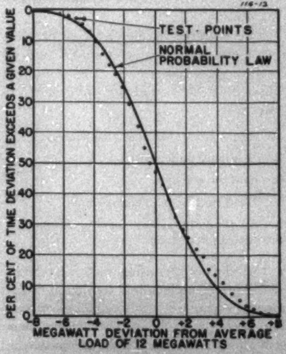

Figure 12. Probability of deviation from average load for typical suburban railroad load

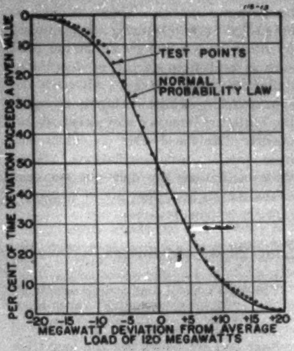

Figure 13. Probability of deviation from average load for typical transit-subway load

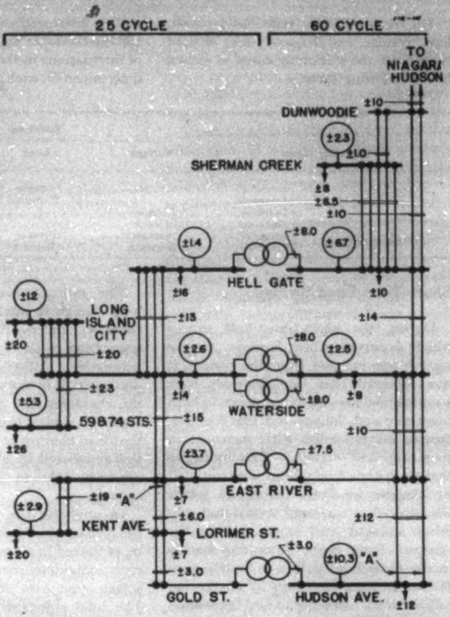
taneously. The generator was placed in operation on the bus in parallel with the system and by means of the synchronizing spring the output was adjusted to 56 megawatts. Then by the auxiliary spring the load was raised 12 megawatts to a total of 68 megawatts. The fusible link was blown while the valve travel and the generator load were recorded. Figure 8 shows the results of this test and indicates that the valve traveled to its new position in about 0.75 second. There was slight overshoot, but there was no tendency to continue oscillating. After the steam valve had reached a steady state a highly damped oscillation of small magnitude existed on the high- and low-pressure units of the generator.

To study governor action further, a group of tests was made in which a generator carrying a unity power-factor load of about 20 megawatts was tripped off the line when the station was tied to the system by one and by two tie feeders and with the Niagara-Hudson system alternately synchronized and separated from the Edison system. The period of the resulting transient oscillations corresponded with the natural period of the system and in each case the amplitude of the swing decreased rapidly. Figure 9 shows typical results of these tests. The oscillations were not sustained or amplified by the action of the governors. Either the governor characteristics or the generator and load characteristics had a very marked damping effect on such transient oscillations. This was further substantiated by a test in which one of two parallel Hudson Avenue tie feeders was opened and closed under load to initiate oscillations. The resultant swing died rapidly in less than two cycles of oscillation indicating that the system has a high degree of damping.

Figure 14. Schematic diagram of the Consolidated Edison system showing fluctuations in megawatts on tie feeders, frequency changers, and generating stations caused by variations in railroad load demands. Hudson Avenue was separated from system during tests by opening switches at A



Additional information was obtained on the contribution of governors to load swings by means of a test conducted with all governors blocked and one tie in service. This tie was opened when carrying about 15 megawatts out of the station. During the test no adjustments were made to the steam valves or generator fields. The station frequency and voltage were allowed to adjust themselves to the load. As shown in figure 10 short-time load swings appeared although the governors were blocked. It is of interest to note that because of the initial 7.5 per cent unbalance in load the station frequency increased 3.8 per cent and the voltage increased 10.1 per cent.

Relation Between System Variables

In these Hudson Avenue tests, it was observed that the generator output, voltage, and frequency fluctuated continuously, varying in period from several seconds to a minute or longer. These fluctuations may be initiated in the following ways:

1. A change in load such as the starting or stopping of a train or a large motor.
2. A change in voltage caused by either manual or automatic adjustments of generator field rheostats.
3. A change in frequency by manual control or by automatic operation of governing equipment.

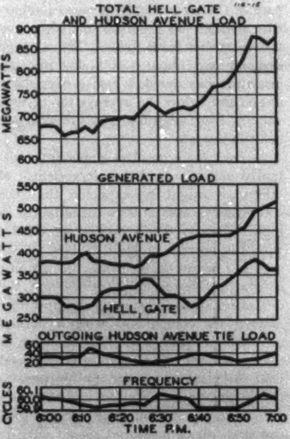


Figure 15. Typical long-time load swings between Hell Gate and Hudson Avenue generating stations

The instantaneous relations between load, voltage, and frequency may be used to indicate the initiating cause as shown in the following table:

Initiating Cause		Effect on		
		Voltage	Load	Frequency
Voltage	Increase		Increase	Decrease
	Decrease		Decrease	Increase
Load	Increase	Decrease		Decrease
	Decrease	Increase		Increase
Frequency	Increase	Increase	Increase	
	Decrease	Decrease	Decrease	

Short-Time Load Swings

During the short-time load swings which occurred when Hudson Avenue station was isolated from the system, it was observed that load increases were accompanied usually by decreases in both frequency and voltage and that load decreases corresponded with increases in frequency and voltage. This indicated that short-time load swings were initiated by changes in distribution load which were traced to the rapid transit and suburban railroad load supplied from the station. Each major generating station in the Consolidated Edison system supplies a substantial amount of fluctuating railroad load. In order to find the magnitude and characteristics of railroad load fluctuations, graphic wattmeter records with a speed of about $1^1/_2$ inches per minute were obtained on typical blocks of suburban railroad load and transit subway load. Figure 11 shows a small part of the record for a section of suburban railroad load during the afternoon transportation peak hour. The average demand was about 12,000 kw but the instantaneous demand varied irregularly above and below the average for periods varying from several seconds to as much as two minutes.

As each train requires power intermittently and is operated independently of others, it might be expected that the composite instantaneous demand of a group of trains would vary in accordance with the normal probability law. Load readings were taken from the graphic charts at five-second intervals and the deviations from the average demand were plotted for comparison with a normal probability curve. The results shown in figures 12 and 13 indicate that railroad load fluctuations appear to conform to the normal probability law and therefore the magnitude of swings for blocks of load similar to those measured should vary as the square root of the average load. For example, if the load is increased nine times the magnitude of the fluctuation will be increased only three times. By this method the approximate magnitude of fluctuations in the railroad load can be determined for each station of this system.

The railroad load fluctuations exist long enough to affect system speed and, therefore, the distribution should be in accordance with turbine governor characteristics. Although individual governors vary, it is probable that the composite characteristic for each generating station is similar to that of the others and that load changes at any point in the system are shared by all generating stations approximately in proportion to their capacities.

In applying the foregoing principles, the magnitude of load swings which would be produced in all parts of the system by each individual portion of railroad load acting separately was first determined. The total swings at any particular part of the systems was obtained by taking the square root of the sum of the squares of the individual swings. Figure 14 shows the calculated maximum load swings which would be expected in each part of the system under normal operating conditions at the time of the maximum railroad load. The calculated values approximate the maximum swings recorded by graphic wattmeters in a number of these circuits.

The sharing by all generating stations of short-time load swings occurring in all parts of the system is a desirable characteristic because the swings on each individual station are less than the fluctuations in the load distributed from the station bus. Although the resulting short-time load swings produce additional heating in tie feeders and frequency changers, calculations show that, in general, this reduces the effective capacity of equipment less than one per cent except in the ties to railroad generating stations where the reduction is three per cent with all ties in service.

Power Oscillations

The Hudson Avenue tests showed that the small two-second oscillations in the generator and tie-feeder loads which appeared only when the station was tied to the system were not caused or maintained by governor action. These oscillations are probably synchronizing swings caused by small sudden changes in the bus load such as result from starting or stopping of individual subway trains. Although the synchronizing swings are highly damped, the initiating impulses may occur so frequently that the system is seldom free from small power oscillations. Since these oscillations are only one per cent of the station load, they are of no importance in system operation.

Long-Time Load Swings

The only type of load swings which affect the operation of boilers and tie feeders and result in undesirable variations in voltage and frequency are the long-time swings lasting five minutes or longer and having a magnitude of five to ten per cent of the station load. These swings can be traced to manual adjustments of the governor valves during periods when the system load is changing rapidly. Examples of such swings are shown in figure 15.

At present the individual station operators have no accurate indication of the operations being performed in other stations so that load is occasionally adjusted manually at two or more stations in a manner to cause heavy tie-line load swings. In order to co-ordinate system operation, a common frequency indicator is being installed in each of the major stations consisting essentially of a synchroscope between a crystal-controlled 60-cycle timing wave common to all stations and the station frequency. The operators at each station with the aid of these instruments will pick up assigned blocks of load in small steps only when the frequency is low and conversely will drop load in small steps only when the frequency is high. By closer control of frequency during the periods of the day when system load is changing rapidly the stations will not endeavor to pick up or drop generator load faster than the system load is changing. Counter adjustment which often results from one station adjusting load so rapidly as to affect the system frequency will be prevented. This will reduce the magnitude of the load swings during the period of rapid load change.

Conclusions

From the results available at the present time, the following general conclusions have been drawn:

1. A reduction in bus voltage will result in the rejection of real and reactive load, and

Power System Governing—the Problem

Synopsis: Considerable attention has been focused on the subject of load swings, turbine generator governing, and stability not only when operating a system alone but when interconnected with other systems. At a subcommittee meeting of the power generation committee, two assignments were made: One to crystallize the problem and the other to outline the desirable functional characteristics of a governing system. This memorandum, dealing with the former, has been prepared based on answers to a questionnaire submitted to a representative group of operating companies. The response to the questionnaire was excellent, practically all of the operating companies to whom it was sent having made replies.

The report is divided into two parts. Part I presents the questionnaire and the replies. Part II gives a discussion of the elements of the problem of governing on power systems.

Conclusions:

1. The general conclusions seem to indicate that there are no outstanding deficiencies in the modern governing systems.

2. It seems likely that full advantage is not being utilized of the inherent capabilities of many existing governors.

3. The full potentialities of governors often are not utilized until some fluctuating load or unusual incident arises which requires that action be taken.

4. A test program is required to disclose maintenance defects, wrong adjustments, and improper operation.

5. The limitations of the speed governor for interconnected operation must be recognized, and means provided to supplement the governor when close control of frequency or tie-line load is required.

Part I

THE questionnaire submitted to the operating companies is reproduced in the first column on chart I. In carrying out the assignment of the subcommittee, the questions were directed at obtaining a cross section of opinion as revealed by present operating practices. The first group of questions serve to define the operating requirements in so far as they are affected by the size of the system, proportion of steam and hydro, type of present governors, roughness of the load, interconnections, etc. A second group of questions serves the purpose of telling how these requirements are currently being met by showing the amount of droop used and the procedure in regulating frequency and tie-line loads. A third group of questions concerns tests made on governors. It was felt the amount of governor testing would furnish a good index of how serious the governor problem has been in the past. There has been some evidence that ordinary measuring devices, such as graphic frequency meters, tachometers, etc., are not fully adequate for checking governor performance, and a question was included to obtain opinions on improved instruments for this purpose. Question 18 was intended to bring out opinions on the adequacy of present governors, and any forward thinking as to the lines along which improvement should be directed.

Chart I tabulates the individual replies while chart II summarizes these answers in a form that the trend can be recognized. A study of these charts is interesting, but does not reveal a well-crystallized statement of the governor control problem. A surprisingly large number report satisfaction with present equipment. On the other hand, most of those companies reporting present governors as essentially satisfactory have fairly steady loads or have made few if any tests. This may indicate that further study and testing would lead to a more uniform and precise expression of governor requirements. It would also appear that more refined testing instruments are desirable.

Part II

The answers to the questionnaire show that, in general, there is no great concern about the operation of the prime mover governors. It is of interest to note, however, that the systems reporting particular interest in governors are those which serve the heavy industrial or electrified railway loads. One such system is interested in the effect of governors on tie-line loads. As the questionnaire has not disclosed any major difficulties, the following discussion of governing problems has been prepared, based on information derived from published articles, informal discussions of operating problems, and information secured from governor specialists. This discussion has been prepared in four sections:

1. Description of the simple speed governor.

Paper 41-68, recommended by the AIEE committee on power generation, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941; prepared through the co-operation of the operating companies listed in the appendix. Manuscript submitted November 13, 1940; made available for preprinting December 14, 1940.

J. J. Dougherty and A. P. Hayward are both with the Duquesne Light Company, Pittsburgh, Pa. A. C. Monteith and S. B. Griscom are with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

---

conversely, an increase in voltage will increase both real and reactive load. A decrease of 10 per cent in bus voltage with the frequency approximately constant resulted in a reduction of 13 per cent in real load and 17.4 per cent in reactive load.

2. Changes in frequency within reasonable limits will not result in appreciable changes in load if the bus voltage is maintained constant. A three per cent change in frequency resulted in no noticeable load change.

3. Continuous small power oscillations of three to five megawatts are present in the tie feeders and generators when tied to the rest of the system. These oscillations have a period of about two seconds and are believed to be synchronizing power swings initiated by sudden changes in distributed load. These oscillations are so small as to be of no consequence.

4. Short-time load swings which have a period of 0.5 to 2.0 minutes appear in the generator and tie-feeder loads and are caused by railroad and transit load fluctuations. Regardless of their origin they are distributed among all generating stations in proportion to the station spinning capacities and amount to less than three per cent of those capacities. These swings have no appreciable effect on the effective capacity of tie lines, generators, boilers, or other equipment.

5. The governors do not contribute to any of the load swings but are operating continuously to maintain the instantaneous frequency within a band of 0.20 of a cycle.

6. The automatic frequency-regulating equipment supplementing the normal governor action has no effect on short-time load swings and synchronizing power oscillations.

7. Transient oscillations on the system such as those caused by tripping a generator or tie feeder are rapidly damped.

8. Long-time load swings are caused by manual operation of governor valves in one or more stations during periods of load change. These are the swings which affect the operation of tie feeders, generators, boilers, and other equipment. By giving the operators in all stations a better understanding of the problem and by providing them with common frequency indicators, it is expected that the long-time swings will be reduced.

Chart I—Answers to Questionnaire on Prime-Mover Governors—

		1	2	3
1	Kw of capacity normally in service for maximum loads?	325,000	511,400	132,500
	(a) Kw of this capacity—steam?	25,000	511,400	132,500
	—hydro?	300,000	None	None
	—Diesel?	None	None	None
2	Kw of steam prime movers having fly-ball governors directly operating the inlet valves?	None	None	None
	(a) Kw of steam prime movers having fly-ball governors with intermediate operating mechanisms (servomotors) between the governor and inlet valves?	25,000	316,500	132,500
	(b) Kw of steam prime movers having fluid governors?	None	222,600	None
3	The no-load, full-load speed regulation varies from a maximum of—%	13.5	5.77	5.0
	(a) To a minimum of—%	1.5	2.25	5.0
	(b) With an average speed-regulation of—%	3.0	3.93	5.0
4	At full load periods what percent of the capacity is operated with blocked governors?	Hydro—100% during high flow; steam—never.	None	11.3
	(a) At light load periods what percent of the capacity is operated with blocked governors?	Hydro—100% during high flow; steam—never.	None	16.6
5	What percent of the operating capacity at full load has automatic combustion control in service on the boilers?	100%	55-full auto. 25-full auto. on air supply only	None
	(a) Percent of the operating capacity at light load?	100%	100	None
6	Are system loads steady?	....		Steady
	weaving?	....	....	....
	rough?	Extremely rough.	Rough	....
	(a) What is the approximate normal load variation during a 15-minute period in percent (plus or minus) of average load?	15.0	6.0	2.0
	(b) If a steel mill, large electric furnace, heavy railroad electrification or other fluctuating load is served and if it affects the load characteristics, describe the type of load cycle in detail.	May get 15% or 75,000 Kw during 2 min. due to steel and railway	During load change may get 11% due to electric furnaces, railway, and rolling mill load	....
7	Have the speed governors been modified or any particular units adjusted to assist or improve the system speed regulation beyond that obtainable with the original governor equipment?	No major modifications. Tests only.	No—Special electric load regulator for 60,000 Kw unit on order.	No
8	Do you operate in parallel with adjacent systems?	Yes	Yes	Yes
	(a) Occasionally?	....	....	....
	(b) Usually?	Always	Yes	Yes
	(c) What is the approximate Kw capacity of the interconnection?	2,500,000	8,500,000	188,000
9	When operating isolated, how is system frequency regulated?	See 8(b)	See remarks	Manually
	, how is tie-line load regulated?		....	
	, how is electric time regulated?		....	
	(a) When operating interconnected, how is system frequency regulated?	By dispatcher of interconnection.	By one of systems in interconnection	Manually
	tie-line load?		Leeds-Northrup	
	electric time?		See remarks	
10	What is the basis and method of allocating load on the various operating units?	Definite blocks according to economy of stations, etc.	Incremental heat consumption, corrected.	Economy
	(a) Does the regulation of frequency or tie-line load conflict with the ideal load distribution?	Yes, almost invariably	No	No
11	Does interconnection with neighboring properties affect your governor practice with respect to number of machines governing on speed?	Yes, dependent upon interconnection.	Not yet	No
	(a) The amount of speed droop?		Not yet	....
	(b) Any other effect?	....	Not yet	....
12	Have you had major difficulties which might be associated with the governing function? For example, pull-out of generating units or generating stations.	No	No but have trouble when isolated due to strip mill.	No
13	Have you had disturbances, not necessarily involving interruption to service, which have caused you to impose limitations on some phase of your system operation and which you feel were associated with governor performance? For example, oscillations hunting any others (a) If such disturbances are traceable to other causes, such as loss of field or low excitation, please distinguish.	No	No	No
14	Do you make any routine tests to determine the speed regulation and speed of response of the governors?	Not reduced to routine matter.	See remarks	Regulation—Yes Response—No
15	Have you made any other tests to determine individual governor performance as a result of hunting or other abnormal operation?	Yes, as required.	Yes, in 1929	No
16	Have you any information derived from governor tests pertaining to governor performance or the variation of the system load with speed and voltage that you can disclose at this time?	Yes, considered of secondary importance on this system.	No	No
17	What type of test instruments have been used for governor tests? (a) How does their speed of response compare with the governor characteristics?	Oscillograph and high speed graphic meters.	Varying from mechanical recorders to magnetic oscillographs (a)—	None made but would use oscillograph if tests were made
18	Are you satisfied with your present governing system?	No	Yes, fundamentally	Yes
	(a) If you are not satisfied, then along what lines should improvements be made?	Frequency regulation	See remarks	....
19	Remarks.		9 Leeds-Northrup frequency regulator 9(a) electric time—By one of system in interconnection 14 Yes, for speed regulation. Tests for speed of response under way. 18(a) To secure same speed of response on various units & adherence to overall speed regulation over load range.	None

2. Limitations of the simple speed governor.

3. Auxiliary equipment required to assist the speed governor in controlling load.

4. Difficulties encountered in the operation of speed governors.

1. DESCRIPTION

The speed governor is used to control the input to a prime mover in such a manner that the speed will be held within definite predetermined limits. The simple governor, therefore, is fundamentally a device functioning directly from speed, and is not responsive to changes in the prime mover output except in so far as the output affects the speed. The governor, being a mechanical device, is subject to all the variations that result from friction and lost motion in the moving parts, making it impossible from a practical standpoint to produce two similar governors with an exact duplication of characteristics. The governors must, therefore, be provided with some means whereby several governors, presumably set for the same speed, can operate in parallel and share the load. The required characteristics are usually inherent in any governor system which is spring loaded, as at any particular speed, the governor will assume a definite position, usually compressing the spring as the speed increases, and permitting the spring to expand as the speed decreases.

The governor is connected by means of links and power cylinders to the inlet valves in such a manner that the inlet valves take a definite position for each position of the governor. In this manner, the governor can be adjusted to hold the inlet valves closed at normal speed and open them as the speed decreases. The amount of speed droop required to move the inlet valves from the no-load to the full-load position is called the speed droop or speed regulation, and is expressed as the per cent speed change from normal speed required to change the output from no load to full load. The per cent regulation is controlled by the design of the governor springs and the ratio of movement produced by the valve linkage.

It is desirable to be able to shift the no-load speed of the governor both to permit synchronizing and to control the output. This is usually accomplished by an auxiliary spring operating in parallel with the main governor spring, the tension of the spring being varied by mechanically moving one end of the spring. The governor does not directly measure the output of the unit, but sets the inlet valves for a certain output which must be attained if the steam pressure and vacuum are normal. The changes in output which result from inlet or exhaust pressure variations will not affect the governor unless these changes are reflected in the system speed.

2. LIMITATIONS

The following discussion has been written from the viewpoint of governor application on a power system and does not attempt to include a discussion of special applications such as exist in many industrial plants. When two or more prime movers, having speed governors with satisfactory speed droop characteristics and ideal performance for isolated operation are paralleled, certain limitations in the operation of the speed governor immediately become evident. Certain of the prime movers, having good thermal characteristics are expected to operate on a base load schedule. The speed governors, however, are continually shifting the load, and in order to adhere to a constant load, it becomes necessary to either block the operation of the governor by load limit devices or partially close the throttle valve. This procedure transfers the load variations to the less efficient units, and also results in a somewhat greater speed change for a given load variation due to the reduction of the governing capacity. It is common practice to use a broader speed regulation on base load units than on the less efficient units. The usual result of those expedients is the restriction of the operation of the governors.

Another limitation of the speed governor appears when a power system forms an interconnection with another power system of much larger size. The speed variations, in general, are a function of the load changes of the larger section of the interconnection as the load variations of the small system are not usually of sufficient magnitude to materially affect the interconnected system speed. The governors on the small system, no matter how excellent their performance, cannot function to follow the true load on their own system. They will, however, attempt to assist the larger system in regulating the frequency, with the result that the load variations in the tie line may be excessive. Again, the usual solution to these difficulties is broadening the speed regulation of the governors on the small system. These governor limitations would not be so apparent if the interconnected system frequency variation were held within narrower limits.

3. AUXILIARIES

There are several main types of auxiliaries that are used either to assist the speed governors, or to counteract the action of the speed governors when their action interferes with proper load distribution.

The speed changer mechanism is an auxiliary device that is necessary on every governor in order to change the speed calibration. The shifting of the no-load speed by means of the speed changer results in changing the valve opening for any given speed, and, therefore, the unit output is changed. From a practical standpoint, the adjustment of the speed changer of any one turbine on a power system, results in a change in output of that unit. The normal load control procedure on a power system is to first observe the system speed; when the speed varies beyond the normal operating band, the speed changers are adjusted so that the load changes are in agreement with a prearranged loading schedule and this manual manipulation tends to correct any drift of frequency from the normal base. Most governors have an overall speed regulation in the order of three to four per cent and if the speed control were left entirely to the governor there would result a speed droop of one to perhaps $2^1/_2$ cycles on a 60-cycle base, depending on the amount of load change. It is, therefore, necessary that during load change periods, the speed changers be adjusted quite frequently in order to hold the system speed within reasonable limits.

Within the last ten years, many systems have installed automatic equipment for the control of frequency and tie-line interchange. The commercially available equipment consists, in general, of contact-making wattmeters or frequency meters connected to the speed changer drive of the governor. This equipment recalibrates certain governors at periodic intervals, provided the quantity being controlled has departed beyond the control point. There are several practical limitations to this procedure, particularly when a system becomes quite large. The operating range of the regulating units is usually not sufficient to take care of the short-time load changes, and the use of any one particular station for regulation may result in abnormal loads on main tie lines. For these reasons, it may be necessary to provide some regulating capacity in each load area. One school of thought suggests that if each load area must provide assistance for automatic regulation that the speed governor detecting the change in speed can best provide this assistance. However, several systems have found by experience that assistance is best determined by the load indication in tie lines

Vol, 194

rather than by frequency. The simple speed governor is unable to identify any such indication, and must be recalibrated as indicated by tie-line interchange to hold the proper load.

There are cases where the conventional speed changer is not adequate for auxiliary control, and special devices have been installed between the speed governor and the valve control mechanism to operate the inlet valves directly from load. The use of topping turbines has introduced the back pressure regulator on main unit prime movers, displacing the function of the speed governor. These special applications will not be discussed as they do not directly pertain to speed regulation.

Experience has shown that where automatic control equipment has been installed in conjunction with the speed governors, and has been able to hold the system speed within reasonable limits, that many of the limitations of the speed governor are eliminated. Base load operation is satisfactory, and yet, the governors are immediately available for any unusual contingency that may arise. Cases where excessive load variations or swings have been attributed to governors under constant speed operation are usually due to one or two governors functioning improperly.

4. DIFFICULTIES

In discussing difficulties that have existed, it should be borne in mind that this discussion covers a summary of the more common difficulties that are likely to exist. However, no one governor will probably have all of these troubles, and no one system will probably have more than a few of the troubles described. There are certain fundamental factors which must be considered when applying speed governors on the turbine. There are definite limitations to the speed of response and sensitivity which are a function of the prime movers and system load characteristics. These factors are well understood by the manufacturers, and in general, it is believed that few governors have been installed which do not meet the minimum requirements.

Some difficulties are now arising in the application of governors where the newer high-speed turbogenerators, equipped with fast governors are operated in parallel with older units with slow governors. Equipment is available for some types of these fast governors to increase their regulation under transient conditions, thereby providing a means of sharing the load swings without interfering with the speed regulation for steady-state conditions.

Another application trouble results from inadequacies of the oil supply for the operating cylinders, making it impossible to provide the required force to move the inlet valves in step with the governor. This condition may exist on some of the older governors, and can be corrected by the addition of oil accumulators. The steady-state operation of the governor will probably not be affected. Many of the older type governors require the governor to furnish the actuating force for the rocker arms and links between the governor and the inlet valves. The forces required to rapidly move these masses may not be available from the governor for load swings or overspeed. It is necessary to add an intermediate relay and operating cylinder to translate the motion of the governor.

The operating difficulties to which governors are subjected are considered to be these troubles that can be remedied by proper maintenance and adjustment. It has been found that the majority of governor troubles fall into these classifications. In many cases, the blame cannot be placed directly on the governor, because after overhaul periods or other work which has required the tearing down and assembling of the governor, no test procedure has been set up to determine that the operating of the governor is entirely satisfactory. The operation of the governors is usually observed for a period after overhaul, but this type of check is mainly of value in detecting hunting.

The most obvious difficulty and the one that is most commonly observed is governor instability or hunting. This phenomenon can best be described as a tendency of the governor to continually maneuver, often without any direct relation to the speed change. This hunting may take place continually or be observed immediately following a speed or load change, after which it is slowly dampened out. Hunting may be due to several factors, such as an extremely fast governor, very sluggish governor, or improper adjustment of the control mechanism. There may also be indications of hunting when fast governors are operating in parallel with slow governors. An analysis of several of these cases has shown that what appeared to be hunting was nothing other than the fast governors accurately following the speed changes by regulating more than their share of the load until such times as the slow machines became active. Some apparent cases of governor hunting are caused by excessive variations in steam pressure which directly affect the output of the turbogenerators. Another example of generator load swings erroneously identified with governor hunting are those caused by electromechanical oscillations between the various generating units, usually induced by load shifts on the transmission system.

The adjustment of the control mechanism can cause hunting by having the speed of response too fast for the inertia characteristics of the generating unit or by overcompensating a sluggish governor. Another trouble that is frequently found, but can be determined usually only by special tests, is an erratic speed droop. Very few steam turbines have a uniform load response for a given speed variation over the entire load range. This is due to fundamental characteristics of the governor operated by centrifugal force, variation in the angularity of the links and rocker arms, and the output characteristics of the inlet valves. Some types of governors are very sensitive to the variations in forces existing on the inlet valves at various openings. On multivalve turbines, the incremental speed regulation usually varies considerably just preceding and after the opening of an inlet valve. In some cases, valve overlaps, which have been determined for purposes of economy, have been reduced to such a degree that dead spots exist in the governor. Another cause of excessive speed droop, which cannot be overlooked, is the change in steam pressure with the change in load.

The speed droop is usually determined for steady-state conditions. However, actual speed droop will change with the rate of load change. It is not unusual to find a governor which shows an over-all speed regulation of four per cent actually operating at a speed droop of 10 to 20 per cent, for load swings such as those produced by a steel mill.

Another major trouble is lack of sensitivity of the governing system either to speed changes or to load adjustments by means of the speed changers. This difficulty is usually the result of excessive friction. A governor with excessive friction may operate satisfactorily when the speed is steady, being erratic in operation only when adjusted by means of the speed changer. This same governor, under a less steady system speed, may show a tendency to creep.

The speed changer mechanism is frequently a source of trouble. In some cases, the relation between revolutions of the speed changer motor and the response of the governor is such that the speed changer motor must operate at high speed for several seconds in order to initiate a load change. The speed changer then coasts for several more seconds, causing overtravel, and making it difficult

Chart II—Prime-Mover-Governor Questionnaire—Summary of Answers of 20 Companies

1 Kw of capacity normally in service for maximum loads?	4 Co's report 1,000,000 or over; 6 Co's 500,000–1,000,000; 9 Co's 100,000–500,000; 1 Co under 100,000.
(a) Kw of this capacity—steam?	6 Co's report over 500,000; 8 Co's report 100,000–500,000; 4 Co's under 100,000; 1 Co "none"; 1 Co wide variations.
—hydro?	7 Co's report "none"; 5 Co's under 100,000; 7 Co's report 200,000–578,000; 1 Co reports wide variation.
—Diesel?	20 Co's report "none"; 1 Co reports 80,000 in frequency changers.
2 Kw of steam prime movers having fly-ball governors directly operating the inlet valves?	18 Co's report "none"; 1 Co reports 40,000; 1 Co reports 4,000.
(a) Kw of steam prime movers having fly-ball governors with intermediate operating mechanisms (servomotors) between the governor and inlet valves?	3 Co's report "none"; 2 Co's report 2,500; 7 Co's 100,000–300,000; 8 Co's in excess of 300,000.
(b) Kw of steam prime movers having fluid governors?	10 Co's report "none"; 5 Co's report 10,000–100,000; 4 Co's report 100,000–220,000. Note—No. 4 Company is 100 per cent hydro.
3 The no-load, full-load speed regulation varies from a maximum of—%	Max. reported of 19 Co's—18%; 1 Co reports 105% (probably 5%).
(a) To a minimum of—%	Lowest min. of 19 Co's is—.02%; 1 Co reports 88% (probably 12%).
(b) With an average speed-regulation of—%	Average ranges from 0% to 7.5%.
4 At full load periods what per cent of the capacity is operated with blocked governors?	13 Co's report "none"; 3 Co's report over 50%; 4 Co's report a low percent, load limits, or special units.
(a) At light load periods what percent of the capacity is operated with blocked governors?	15 Co's report "none"; 2 Co's report app. 15%; 3 Co's report load limits, or special units only. Hydro units: During high flow periods.
5 What percent of the operating capacity at full load has automatic combustion control in service on the boilers?	6 Co's report "none"; 2 Co's 100%; 11 Co's range from 16% to 70%.
(a) Percent of the operating capacity at light load?	7 Co's report "none"; 3 Co's 100%; 3 Co's report 90%; 6 Co's 30% to 80%. Note—No. 4 Co is 100% hydro.
6 Are system loads steady?	12 Co's report "steady".
weaving?	3 Co's report "weaving".
rough?	2 Co's report "rough"; 2 Co's "moderately or extremely rough"; 1 Co reports between "weaving" & "steady".
(a) What is the approximate normal load variation during a 15-minute period in percent (plus or minus) of average load?	10 Co's report 3% or under; 4 Co's report 5% to 7 1/2%; 4 Co's report 15%–20% including morning pick-ups; 1 Co slight.
(b) If a steel mill, large electric furnace, heavy railroad electrification or other fluctuating load is served and if it affects the load characteristics, describe the type of load cycle in detail.	The 4 Co's reporting "rough", or "extremely rough" report { 75,000 in 2 min. or 15%. 11% in 15 min.—total load 511,400 Kw. 40,000 Kwchange—noperiod given. 20% no period given. 1 Co reporting "steady" has abrupt 2–3% change on interconnection. 1 Co reporting "weaving" has 2 1/2% minute to minute variation.
7 Have the speed governors been modified or any particular units adjusted to assist or improve the system speed regulation beyond that obtainable with the original governor equipment?	15 Co's report "No"; 5 Co's report modifications on specific units; 1 Co reports load regulator on order.
8 Do you operate in parallel with adjacent systems?	17 Co's report "Yes"; 2 Co's report "No"; 1 Co does not answer question.
(a) Occasionally?	No company reports "occasionally".
(b) Usually?	10 Co's report "Usually"; 1 Co—"normally"; 7 Co's report "always".
(c) What is the approximate Kw capacity of the interconnection?	Of 10 Co's who interpreted this question correctly, all reported 1,000,000 to 25,000,000; the 7 others operating interconnected, apparently reported tie-line capacity only.

for the operator to properly estimate the load change. This condition can be improved by reducing the load on the speed changer motor and then changing the speed of the motor so that the motor inertia is not a controlling factor. These difficulties usually are not serious when operating with hand control, but are very evident when automatic frequency or tie-line control is applied.

There appear at present to be four factors which need additional consideration from an application standpoint:

1. Means of adjusting the speed regulation both for steady-state and transient conditions to permit co-ordination of the newer governors with the older governors.
2. Further reduction in the incremental regulation from minimum to maximum load and the elimination of dead spots.
3. Improvements in the speed changer mechanism to provide the required sensitivity and uniform response.
4. Provision for decreasing the speed regulation of the governor within the continuous maneuvering range.

This last suggestion may be subject to some difference of opinion, but is based on the following thought. The system load can be broken down into three components. The fundamental component represents the short-time load variation that has a period lasting from several minutes to an hour or more. This component is easily distinguished by observing the weaving line on the frequency recorder. The second component is the short-time variation which is observed on the frequency recorders as the frequency band. This may vary from a few hundredths of a cycle to several tenths of a cycle, depending on the size of the system and the character of the load. These variations occur every few seconds and many systems, using automatic control, consider it best to have the control inoperative in this range and rely on the system inertia and governors to provide the regulating effort. Applying the same reasoning, the speed governor would have normal sensitivity in this range, but the control mechanism would be damped to prevent excessive operation of the inlet valves until either the speed error exceeded this limit, or errors within the limit existed for an excessive length of time. The third component is due to very short duration load changes due to line switching, motor starting, etc., and these are rarely reflected in the system frequency.

Several systems, which have investigated governor performance at various times, have been convinced that many of the troubles can be laid to inadequate maintenance of the governors. On the other hand, there is evidence that something less than perfect governor performance may still be satisfactory where the steadiness of the load does not demand exceptionally close governing. Governor tests have shown that many of the gover-

9	When operating isolated, how is system freq. regulated?	5 Co's report "manual"; all others report "manual", "automatic" or special instrument.
	, how is tie-line load regulated?	Of those answering directly, 4 Co's report "manual"; 1—by Dispatcher; 2—Instrument; 2—by Governor.
	, how is electric time regulated?	Similar to frequency in most cases.
	(a) When operating interconnected, how is system frequency regulated?	6 Co's report "manual"; 3 Co's report "special instrument"; 2 by large station; 5 by system dispatcher or by one system.
	Tie-line load?	4 Co's report "manual"; 2 Co's report "special instrument"; 2 by large station; 1 by Blocking; 6 by Dispatcher or one system.
	Electric time?	6 Co's report "manual"; 3 Co's report "special instrument"; 1 by large station; 5 by Dispatcher or one system. Note—One Co reports whole question under consideration, another Co gave no answers.
10	What is the basis and method of allocating load on the various operating units?	8 Co's report "station economy"; 9 Co's report some form of incremental loading; 1 base load on some, others swing; 1 water rate; 1 simply by percentage of total load.
	(a) Does the regulation of frequency or tie-line load conflict with the ideal load distribution?	4 Co's report "Yes"; 8 report "No"; 3 report—occasionally; 2 report—to minor extent; 1—no answer.
11	Does interconnection with neighboring properties affect your governor practice with respect to number of machines governing on speed?	15 Co's report "No"; 3 Co's report "Yes".
	(a) The amount of speed droop?	15 Co's report "No"; 3 Co's report "Yes".
	(b) Any other effect?	20 Co's report "No". Note—2 Co's do not operate interconnected.
12	Have you had major difficulties which might be associated with the governing function? For example, pull-out of generating units or generating stations.	17 Co's report "No"; 3 Co's report occasional trouble due to mills or interconnection.
13	Have you had disturbances, not necessarily involving interruption to service, which have caused you to impose limitations on some phase of your system operation and which you feel were associated with governor performance? For example, oscillations	17 Co's report "No"; 1 Co reports a single slow governor; 1—interconnection instability;
	hunting	1 Co sent charts showing weaving frequency.
	any others	1 Co reports one improper governor action—picked up full load.
	(a) If such disturbances are traceable to other causes, such as loss of field or low excitation, please distinguish.	
14	Do you make any routine tests to determine the speed regulation and speed of response of the governors?	9 Co's report "No" to both parts; 6 Co's report routine speed tests, generally with overhaul of unit; 5 Co's report speed tests "as required". Few companies report initiation of speed of response tests.
15	Have you made any other tests to determine individual governor performance as a result of hunting or other abnormal operation?	12 Co's report "No"; 7 others report "as required" or "occasionally"; 1 Co reports tests in connection with automatic control equipment.
16	Have you any information derived from governor tests pertaining to governor performance or the variation of the system load with speed and voltage that you can disclose at this time?	15 Co's report "No"; 2 Co's report published data; 1 reports tests in progress; 2 for particular units.
17	What type of test instruments have been used for governor tests?	7 Co's report no instruments. 6 Co's report tachometers or 1 speed indicators 4 Co's report oscillographs and/or graphic meters 1 Co reports photocell and steam indicators
	(a) How does their speed of response compare with the governor characteristics?	Part (a)—Only 4 Co's answer as follows: 1—equally fast (oscillograph & frequency meter) 1—very satisfactory (photocell & indicators) 1—faster (long film oscillograph) 1—unknown (hand tachometer)
18	Are you satisfied with your present governing system?	12 Co's report simply "Yes"; 2 Co's report "No"; 6 others qualify answer such as "fairly so", "reasonably so".
	(a) If you are not satisfied, then along what lines should improvements be made?	Frequency regulation; similar response and speed regulation over load range; load regulation; prevent swings; increased sensitivity; reduce average speed regulation.

nors which appeared to be satisfactory were not functioning properly. The main difficulties were found to be excessive friction, improper adjustment of intermediate relays, and improper setting of valve cams and compensators.

A few governors are operating today which are entirely inadequate for the duties required of them. These governors can be modified or rebuilt to meet the required standards if and when it can be proved that the expense is justified. In some cases, as long as the governor protects the turbogenerator, it has not been deemed advisable to expend the funds required to accomplish the niceties of speed regulation.

There has been very little said in the above discussions of how well the present governors are doing their job. Many of the faults of governors have been mentioned for two reasons: to summarize the various types of troubles that have occurred in order to provide a basis of attack for analysis of trouble or conduct of test, and in order to form the basis of a discussion. It is not believed at this time that there are any major deficiencies in the governing system. A few systems have recently experienced some large industrial loads, which have made the existing governing system seem inadequate. Other systems have experienced difficulties in tie-line interchanges and the correlation of steam and hydro governors. These problems require much thought and effort for their solution, but this is gradually being accomplished. A few years ago, much reliance was placed upon the use of automatic frequency control, and no doubt the interest in this type of equipment has caused some relaxation of attention to the speed governors. Lately, many operators are returning to the thought that the speed governors are the fundamental speed regulating equipment, and the automatic frequency control is only a vernier control. It is obvious that very few of the automatic frequency control installations are able to cope with any sudden or large load changes without the assistance both of the governors and the operators.

A discussion of load swings has been included in the program. This particular load characteristic has become of more importance in the last few years due to the increasing use of utility service for the supply of the high-speed continuous strip mills, heavy railway electrification, and large electric furnaces. The utilization of power for many of these loads might be impractical without the interconnected capacity made available by the utilities.

The continuous strip mill has a periodic cycle, more or less regular in form, which has the characteristic of increasing from a minimum to a maximum in a relatively few seconds, then holding the load for 10

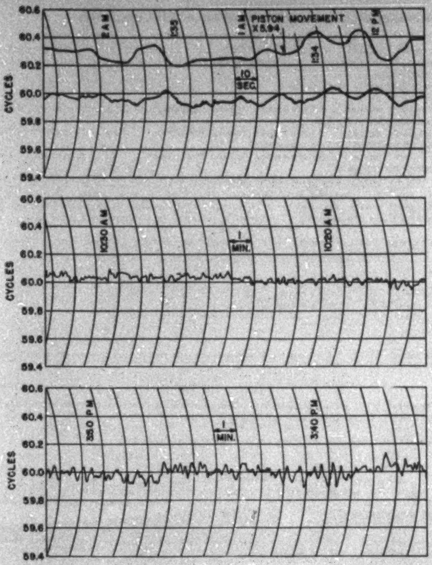

Chart III

or 20 seconds, then rapidly dropping the load. This cyclical type of load is particularly hard to handle because the rates of change are very fast, and the load pickup does not exist for any length of time. The railroad loads, are, at times, as severe as the strip mill loads in so far as rate of pickup is concerned, but do not occur at periodic intervals; therefore, in general, they are somewhat easier to control. The electric furnace load, while not reaching the magnitude of either the railroad or strip mill load, is particularly vicious due to its instantaneous rate of change.

The effect of these loads on system performance varies according to the system setup, and the location of the swinging load relative to interconnections and power stations. An isolated system will experience speed variations, which, at times, are too fast for the governors. Voltage variations often accompany the speed variations and high-speed voltage regulators cannot completely eliminate the voltage variations. These voltage variations result in great activity of the induction voltage regulators. When the system operates interconnected, the speed variation is not so pronounced, and the voltage variations caused by the change in kilowatt load are reduced. However, tie-line control is then a problem. The load swings on the tie line may considerably restrict the safe operating capacity of such an interconnection due to the reduction in average load to hold the maximum load swings within the safe operating limit. The transfer of these load swings through adjacent systems may also introduce operating difficulties. These load swings, as they pass from one interconnection to another, sometimes tend to amplify as the distance away from the origin increases. The presence of these swings in the interconnection is due to the inability to rapidly readjust the generator outputs to compensate for the load swings, and their relative magnitudes are due to the electromechanical characteristic of the power systems. For instance, if a sudden increase of load occurs on system *A*, the initial load swing is partly supplied from the stored energy in system *A*, while its phase displacement is retarded in respect to system *B*, the rest of the load swing is supplied through the interconnection from system *B*. The amount of stored energy released is a function of the load-angle characteristic of the transmission system, including the tie line.

It has been observed that if the governors are immediately readjusted to pick up exactly the same amount of power as is flowing through the tie line, that an appreciable time lag will occur before the tie-line load has returned to normal. This lag may be as great as 15 seconds. A similar phenomenon has been observed when actuating the load shift by means of a phase-angle regulator. This characteristic ordinarily prevents the use of fast response load regulators due to the tendency to hunt. This energy must be returned to the system to advance its phase displacement before the tie-line load can be returned to normal.

Fast tie-line load regulators of the impulse type may be more harmful than advantageous due to the time lag required to readjust the governors. Often the load swings are amplified to twice the original amplitude by action of the load control.

One solution that is being tried is based on utilizing the diversity in load swings between two adjacent systems. The fringe of the adjacent system load is transmitted by telemetering and superposed on the regulated tie line. This procedure permits load variations to exist on the tie line between the two systems which tend to counteract load swings on the adjacent system, and also tends to accelerate the action of the load control when the load swing appears on both interconnections. It has been found desirable to utilize system inertia as much as possible to provide the regulation for the cyclical and other rapid load variations, using automatic control to center or average the speed or tie-line interchange.

Appendix

Excerpts of Complete Answers*

Company 1

Answer 3. Figures of speed droop have a varied and uncertain basis. It is, therefore necessary to be very specific when dealing with this subject. Our steam units have a special device whereby the amount of speed droop can be varied by remote control while the machine is on the line. According to the manufacturer's data, this speed droop at full load can be varied from 1.5 per cent to 7.5 per cent. The present setting is such that the speed droop at full load based on the manufacturer's data showed about 4.5 per cent. These foregoing figures we would, for want of a better term, call the "steady-state speed droop" to distinguish them from the following: by actual test on the machines while running on the system with the above speed droop setting, we find that we have an actual speed droop of about 13.5 per cent which we might call the "dynamic" speed droop.

Answer 6. The system loads are extremely rough. The normal load variation during a 15-minute period is no worse than it might be in a 2-minute period and is approximately plus or minus 15 per cent of the average load. There are large steel mills and heavy railroad electrification on the system; the steel mill cycle is such that we get a peak of from 20,000–25,000 kw once a minute, and the railroad variations are extremely indeterminate both as to time and amount, i.e., they may occur almost any time and the variation may be 50,000 kw in two minutes. The combined *variation* may be occasionally 75,000 kw.

---

*Note: These are excerpts from original answers as abstracted for tabulation.

Answer 8. (*a*) and (*b*)—Our system always operates in parallel with two adjacent systems. These three systems are operated as one group as far as economic generation is concerned; this group in turn has interconnections with systems to the north and east.

(*c*)—The total capacity in normal operation of all the groups mentioned is about 2,500,000 kw which includes about 250,000 kw in hydro capacity, which is in addition to our hydro previously mentioned.

Company 2

Answer 6. The system loads are rough. The normal load variation during a 15-minute period is approximately 6 per cent of the average load. However, during load change periods, the 15-minute variation may be as high as 11 per cent of the average peak load. This system supplies many electric furnaces and a large traction load. There is no evidence that these particular loads have introduced any governing problems. There is also a steel mill supply for an 80-inch continuous strip mill which has noticeably affected the governing requirements of the system. A typical load cycle on this mill will vary between the following limits:

(a)		(b)	
Load—Megawatts	Time—Seconds	Load—Megawatts	Time—Seconds
0	0	0	0
20	20	20	10
20	60	20	20
0	80	0	30

These cycles are repeated at periodic intervals averaging between 8 to 12 cycles each 15 minutes.

Answer 17. What type of test instruments have been used for governor tests?

Various types of instruments have been used for governor tests from straight mechanical recorders to magnetic oscillographs.

At present, governor investigations are being conducted with a standard strip chart wattmeter with minute chart speeds and a photoelectric frequency recorder with a similar chart drive. Each of these instruments is equipped with two auxiliary motion recorder pens. The damping of the wattmeter is adjusted to cause the meter to settle at the correct load without overshooting or hunting within one second following a sudden load change. Although this meter is not particularly fast, the damping effect of the inertia and phase-angle characteristics of the turbogenerator make this response adequate. The frequency recorder has a time lag not in excess of 0.2 second for a full-scale change in deflection.

Great care must be taken when using oil pressure recorders to insure that the natural period and damping of these devices is properly chosen to suit the pressure fluctuations to be recorded.

Answer 18. Are you satisfied with your present governing system?

The present governing systems fundamentally meet the requirements of a speed controlling device. Many of the older governors, however, are not capable of meeting the changing requirements as the systems have grown. Certain types of governors are inherently sluggish and do not assist in system regulation. On the other hand, those governors which have been active and sensitive have often been deliberately adjusted to destroy their sensitivity in order to reduce the burden on the boiler rooms.

Major improvements which appear to be desirable in the governing system are means to provide the same speed of response on the various units to give accurate load distribution during transient speed variations, and improvements in the control mechanisms and inlet valves which will result in closer adherence to the over-all speed regulation along the entire load range of the units.

Company 5

Answer 13. Have you had disturbances, not necessarily involving interruptions to service, which have caused you to impose limitations on some phase of your system operation and which you feel were associated with governor performance? Yes. Cannot operate number 5 unit as a single unit on the system.

Answer 16. Have you any information derived from governor tests pertaining to governor performance or the variation of the system load with speed and voltage that you can disclose at this time? See description of trouble.

Answer 18. Are you satisfied with your present governing system? If not, along what lines should improvements be made? All except number 5. This governor is too slow for light swinging load when operating with one condensing unit and steam heat load. Governor permits wide speed swings.

13, 16, and 18—Description of Trouble. Unit 5, a 10,000-kw, 25-cycle, 600-pound turbine, is noncondensing, exhausting into a 185-pound steam header which supplies steam heat systems; 2–10,000-kw, 25-cycle units; or 1–26,000-kw, 60-cycle unit. The 2–10,000-kw, 25-cycle units, also the 26,000-kw, 60-cycle unit can be operated from the 600-pound header through a reducing valve. The 25-cycle system load varies over the 24-hour period from 2,000-kw night load to a maximum of 28,000 kw. The difficulties arise on the light load periods. The governor of unit 5 is too slow for a light swinging load when operating with one condensing unit and steam heat load. Ordinarily the 25-cycle system is connected to the 60-cycle system through 2–5,000-kw frequency changers. At all times when the changers are in operation, no difficulty is encountered due to load swings or hunting between units. On the 25-cycle system at light load periods, the normal swing in load is from 1,000 to 1,500 kw.

With unit 5 operating in parallel with one of the 10,000-kw, 25-cycle units and without the frequency changers the load swings start a frequency variation ranging from 24 to 26 cycles. It is accumulative and has tripped unit 5 on overspeed. The governor regulation of unit 5 has been changed to 8 per cent no load and $4^{1}/_{2}$ per cent full load without satisfactory results. The governor oil pressure has been increased and decreased above and below normal without satisfactory results. To date we have found no correction which is satisfactory.

Company 10

Answer 9. The system frequency and electric time regulation is combined as one operation and is usually regulated by one of the larger generating stations of the interconnected system, with the understanding that on a predetermined low- or high-frequency value all generating plants that are operating interconnected will make adjustments to the frequency to bring the frequency to a normal value as quickly as possible. Tie-line regulation is accomplished by the load schedule set up for the interchange of power in the desired direction in accordance with the economical costs.

Company 12

Answer 12. Unsatisfactory governors cause machine loads to fluctuate unnecessarily resulting in loss of economy on steam equipment, excessive manipulation by the operators, and giving a speed curve which swings as much as 0.15 cycle with a period of 15 to 20 seconds. Chart 3 shows a period of typical operation and a much better period when one 50,000-kw and 2–75,000-kw steam units were operating against stops, and one of the two hydro plants was regulating frequency. The third graph shows the operation of the governor on one of the 75,000-kw units that was causing swings of system speed. This governor had a time lag on the reversals of about four seconds.

Company 14

Answer 9. Either system *A* or system *B* regulates frequency depending on conditions:

1. When system *B* is regulating, the governor of one of the turbines so equipped is controlled by a Leeds and Northrup instrument operating on flat frequency. System *A* maintains a predetermined load transfer on the ties by load regulation. Time is maintained by a device used in conjunction with the Leeds and Northrup controller which changed the neutral point of the controller in proportion to the cycles deviation from perfect time obtained from a crystal oscillator.

2. When system *A* is maintaining frequency they operate on flat frequency and system *B* maintains tie-line load transfer by operating on selective frequency control.

Answer 17. A long film oscillograph is used for measurements, about seven inches of film covering one second. The instrument response is evidently quicker than the response of the things we are measuring since, when changes are made, a gradual change is shown by the photographic record. As an example: the film of the test mentioned in question 15 showed the valve travel on the generator gradually decreasing to a point shortly below its steady state and then increasing a small amount to its final steady value. The total time from the instant of fusing the link to a steady state of valve travel was $^{1}/_{2}$ second and generator load was steady in $2^{1}/_{4}$ seconds.

Company 15

Answer 1. This group of systems is served by a combination of hydro and fuel plants and capacity received from foreign systems on either purchase or exchange bases. The amount of capacity normally in service, therefore, varies within wide limits with seasonal stream flow conditions. Energy requirements, and not short-time peaks, set the goal for capacity. In other words, if the required amount of energy over periods of 16 hours a day for 5 days a week can be met there is little likelihood of any shortage of capacity to carry hourly peaks. When there is plenty of water hydro plants are loaded to capacity with the exception of those assigned to frequency or tie-line control and steam plants and capacity received from other systems, is at a minimum. During dry seasons greater capacities in steam plants are operated to conserve water, and since practically all the hydro capacity is spinning, though not loaded, the total capacity available to carry peaks is much greater than during wet seasons. In transition periods from seasons of plentiful water supply to those when water must be conserved steam and hydro capacity operated varies greatly and the amounts are difficult to express specifically.

The following statement is an attempt to express the conditions prevailing during 1939.

January was unusually dry, and considerable steam was operated, but from February through June stream flows varied from medium to high, which is representative for this season. Monthly peak loads were of the order of 725,000 kw and the capacity in service, some 800,000 kw, of which 725,000 kw was in hydro, 50,000 kw in steam, and 25,000 kw in receipts from other systems. The amounts, expressed in per cent of total, were hydro 91 per cent, steam 6 per cent, and receipts 3 per cent.

During the transition period from July to September loads were some 800,000 kw and the capacity in service, 900,000 kw, the relative amounts being 640,000 or 71 per cent hydro, 200,000 or 22 per cent steam, and 60,000 or 7 per cent receipts from other systems. The dry season lasted from September through December and, in fact, extended into 1940. It was remarkable for its duration, rather than its severity, two other years (1925 and 1931) having had much lower flows. Loads were of the order of 850,000 kw, the peak for the year being 880,000 kw in December. Capacity in service totaled approximately 1,000,000 kw, the relative amounts being 600,000 or 60 per cent hydro, 300,000 or 30 per cent steam, and 100,000 or 10 per cent receipts from other systems.

Answer 4. At full load periods 100 per cent of the steam capacity is operated with blocked governors. At light loads 100 per cent is operated with blocked governors. All of the hydro plants, except the one designated to control frequency, either have their governors blocked so as to prevent the units from increasing their load, or have the port in the governor dash pot reduced to such a small opening that the response is very sluggish to a change in frequency.

Answer 10. Load is allocated to hydro or steam plants in accordance with stream flow conditions primarily. Steam plants are put into operation in ascending order of cost, and those operated are usually fully loaded throughout the peak period of 80 hours per week. Load is assigned to hydro plants on the basis of availability of water, stream flow plants being based during wet seasons and peaked in dry seasons, the operation of storage fed plants being the opposite.

Company 20

Answer 12. System instability has been experienced a number of times in recent years. Every case has been attributed to sustained low voltage, either produced by a sustained system fault or inability of the system to pick up the required quantity of inductive reactive load following the loss of generation. Such periods of instability are characterized by very violent hunting and violent pumping of the governors. In some cases the oscillograph records show traveling phantom faults, indicating that generators or generating stations are out of step with the rest of the system. In every case the system has pulled out of its troubles without losing load other than that lost with the fault by the process of applying maximum field strength to the generators and simultaneously running the governor motors to reduce load on all machines on which all instruments were vibrating over the full scale. Stability has generally been recovered without dropping additional load in some two to five minutes. It is important to note that the turbine operator, during periods of instability and violently pumping governors, seizes the governor rods by hand so as to prevent, or at least greatly reduce, the violent pumping.

Answer 13. On several machines which were found to be unstable, governor nuts were turned down to prevent the machines from taking maximum load. Also, orders were given to the operating department that these unstable machines were to be operated always at full field. The other machines on the system are operated with field currents never less than sufficient to give them a pull-out torque of 150 per cent of maximum load, that is, the pull-out torque against an infinite bus never comes to less than 150 per cent of the load the machine can carry with governor wide open and with normal steam conditions.

Field adjusters are being installed on all generators following a successful trial installation and it is expected that these field adjusters will automatically apply and maintain the maximum possible generator field strength during all periods of instability.

Where it is desired to carry high power factor on a machine having low "steady-state" stability, it is proposed to supply an autotransformer to raise the maximum voltage so that it may continue to operate at a strong field.

Answer 18. Three new 50,000-kw generators are being equipped with resynchronizing governors; two of these machines are being installed in a station some 80 miles from the main group of our generating stations and while these two machines have very good "steady-state" stability, it is believed that they will be liable to fall out of step with the distant system since the local load they carry is relatively small with respect to the load transmitted to the system. It is hoped that the resynchronizing governors will bring these machines into synchronism quickly following an out-of-step condition and that it will never be required that they be disconnected and resynchronized. This same out-of-step governor is being installed in one 50,000-kw topping unit now being installed in one of our generating stations, that is, this machine is being installed on a bus of such low reactance that it may be considered for all practical purposes as connected to an infinite bus.

Note: Experience indicates that, following a sudden drop in frequency, the governor of a machine having low "steady-state" stability will open up faster than a field adjuster will strengthen the field so that the pull-out torque of the machine may be exceeded.

Effect of Prime-Mover Speed Governor Characteristics on Power-System Frequency Variations and Tie-Line Power Swings

E. E. PARKER
NONMEMBER AIEE

Introduction

IN the normal steady-state operation of a power system, proper load division, frequency, and time are maintained by manual or automatic system control, while the transient swings occasioned by load changes are absorbed by the inertias and speed governors of the individual generating units. With improvements in reliability and performance of systems and their interconnections, it is a natural development that further careful attention and study be given to the basic speed governors and their effects on system operation.[1,3,4] It is desirable to determine the requirements which a good governing mechanism should fulfill, and the effects of specific governor and system characteristics on over-all system performance. Moreover, under certain conditions some governors may accentuate rather than reduce the magnitudes of the frequency swings, and it is desirable to know the conditions for which this may occur.

The purpose of the present paper is to present the results of an analytical investigation of some of the effects of governing system characteristics on power system performance, and to relate the conclusions drawn from this work to those presented in the companion paper.[4]

Conclusions

The following general conclusions have been drawn.

1. Reduction of dead band, avoidance of too small a regulation, either transient or steady-state, and proper proportioning of the response of the various elements of the governing mechanism tend to improve stability, so that a system will have a maximum tendency for a rapid settling down of frequency and load after a load change and a minimum tendency for the support of a sustained frequency variation. The over-all dead band of the governing mechanism of a prime mover including governor head, hydraulic relays, and valve gear, rather than that of any one particular element of the governing mechanism, is of importance in determining the governor stability characteristics.

2. System characteristics have an important influence on the frequency stability. Load damping (net change of system electrical load and input torque with frequency) and the electrical damping between generators and parts of the system contribute very greatly to stable operation. (The amount of load damping required to assure stable operation regardless of the rate of governor response is inversely proportional to the speed regulation.)

3. The frequency stability of either of two systems may be either improved or lessened by an electrical interconnection, depending upon the magnitude of the tie-line electrical damping.

4. Interconnection of two power systems with good frequency stability may introduce some instability if there is little damping in the tie line. For small tie-line and small load damping, sustained self-excited oscillations can be set up in a system by dead band in the governing system for a considerable range of system parameters. Frequency oscillations at the tie-line natural frequency (producing a tie-line power swing) and at a lower frequency determined by the governor characteristics may be simultaneously excited by dead band in the governing system. On the other hand, considerable damping of larger tie-line power swings may be produced by governor action when these swings cause frequency variations outside the governor dead bands.

5. For machines in service unnecessary system frequency movement or oscillation caused by governing can be most easily and effectively reduced by reduction of dead band and broadening of the regulation of the governor mechanisms on the units tending to cause the unnecessary movement.

6. Steam turbine generators, because of the smaller time lags associated with governing steam flow as compared with water, are inherently capable of producing a greater stabilizing influence on system frequency than are hydro generators.

Discussion of Results

STABILITY

One of the desirable characteristics of a governing system is that it should respond to load changes and settle down to its new operating position with the least possible disturbance. This means that it should be as stable as possible. Therefore the first aspect of governor performance studied was the effect of the various parameters on system frequency stability. The problem of the stability of governing

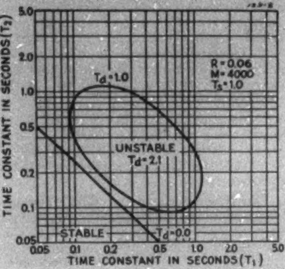

Figure 2. Machine tied to large system

Effect of governor time lags and load or tie-line damping on stability

systems is about as old as governing itself, and, at least in the case of prime-mover governors, has been studied for many years, the first analytical investigation having been reported in 1868 by J. C. Maxwell.[3] The particular contribution of the present work is in showing the effects of the power-system characteristics and of governor dead band.

SINGLE MACHINE

As the simplest approximation to a speed-governed power system the system generating capacity was lumped as a single equivalent machine, having an inertia and a load damping characteristic, and governed by the idealized type of speed governor described in the appendix. Such a mechanism represents the behavior of a steam governor somewhat more exactly than that of a hydro governor having a droop compensation mechanism. Two first-order time lags in the governing mechanism were used because two is the smallest number which will result in the proper qualitative behavior. That is, a governing system whose lags are all lumped into one time constant does not have the possibility of instability exhibited by an actual governing system, while one with two time lags does. For example, a governing system with no lag between speed change and inlet valve position would operate stably even with a large lag due to stored steam or water. As far as stability is concerned, it is because of the inherent physical limitations in the possible speed of response of mechanisms, that a slow rather than a fast response governing system must be used in some cases. Moreover, in the case of water turbines the valve response must be slow because of the water conditions which might otherwise arise during large and rapid gate movements.

Figure 1 shows the results of stability calculations made for this simple system. It is seen that if one of the governor time constants T_1 is made sufficiently small, the system is stable regardless of the value of the other time constant T_2. For a given degree of stability, the allowable total time constant T_1+T_2 is smallest when the two time constants are equal. This result is consistent with the statement that there could be no instability with only one time constant. In general, the fewer the number of stages (and consequently the simpler the mechanism) for a given total time lag, the more stable is the system.

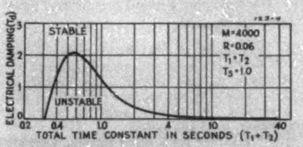

Figure 4. Machine tied to large system

Effect of governor time lag on load or tie-line damping required for stable operation

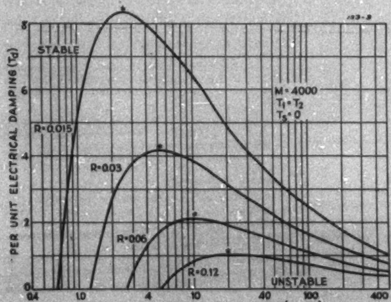

Figure 3. System or single machine

Effect of governor time lag and regulation on load damping required for stable operation

NOTE: Maximum points occur at time (in radians) $T_1=T_2=8RM$, and at damping $T_d=1/(8R)$

Figure 1 further shows that when there is load damping, the system may be made stable by either increasing or decreasing one or both time lags, and that if the load damping is sufficiently great $(T_d \geqq 1 \div (8R))$ stability is obtained regardless of the governor lag. The condition of synchronizing a machine corresponds closely to that of zero damping and no electrical tie, $T_d=0$ and $T_s=0$, and is the least stable condition shown in figure 1.

Figure 2 shows the effect of a synchronous tie between the machine of figure 1 and an infinitely large system, when the tie-line damping is small or zero. Much faster response is required for stability, but the amount of damping required to prevent any instability is not affected appreciably.

It is interesting to note that if there exists small damping either electrical or mechanical, as for example in a salient-pole generator with no amortisseur winding connected to a system at light load, the unit may be more unstable than under the condition of synchronizing (figure 1, $T_s=0$, $T_d=0$). This has been observed in the field and indicates the desirability of amortisseur windings for salient-pole machines. Usually the electrical rotor damping is sufficiently large so that the operation of a single machine connected to a large system is more stable than that of the same machine isolated, or of the entire system operating against the load damping.

The results obtained with two time lags tend to be somewhat more stable than those which would be found for an actual governing system having more than two lags. Therefore, for further study the least stable case, equal time lags, was selected. Figure 3 shows for this case and for the system of figure 1 the effect of regulation on the load damping required to produce stable operation as the time lags are varied. As regulation is increased the allowable range of time lags increases and the required amount of load damping decreases. Moreover, as regulation increases the effect of moderate amounts of load damping $(T_d \leqq 2)$ in allowing longer response times becomes much greater. The effect of regulation on stability is also seen in figure 14, which gives a comparison of the rates of decay of the frequency oscillations caused by a sudden load change, for three different regulations.

Figure 4 shows the required damping torque T_d for the case of $T_1=T_2$ when a machine is connected to a large system through a synchronous tie $(T_s=1.0)$. This curve, when compared with the curve for $R=0.06$ of figure 3, shows the

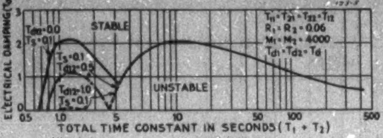

Figure 5. Two interconnected systems or machines

Effect of governor time lag and tie-line damping on load damping required for stable operation

effect of the synchronous tie in changing the range of required time lags for stability. These results show the influence of governor regulation, electrical damping, and synchronizing torques on the stability of the system. Since the electrical damping available is usually limited and determined by system conditions, the results show the desirability of reasonably broad transient regulation.

Just as figures 1–4 show that system electrical damping is required to compensate for the tendency toward instability caused by large time lags in the governing system, calculations have similarly shown that with small time lags the governing system may contribute considerable damping. It may be shown that the possible contribution of the governing system becomes greater as the time lags are reduced, and that for any given speed of response there is an optimum range of governor regulation (which is not however very critical), for maximum damping effort. Because optimum regulation is more or less proportional to the time lag, steam units are inherently capable of a greater system frequency stabilizing influence than hydro units. Field experience seems to bear out this conclusion, and to indicate that for reasonably fast response governors the optimum regulation may be of the order of six per cent.

Interconnected Systems

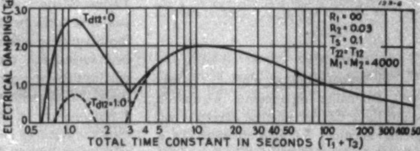
If two similar systems are connected together through a tie line it is evident that they can vary in speed together as one machine or that the two systems can oscillate against each other about a point in the middle of the tie or that both modes of oscillation can occur simultaneously. Thus we may expect to find an unstable region corresponding to that of figure 3 and also one corresponding to that of figure 4 with half the tie-line reactance (twice the synchronizing torque coefficient). Figure 5 bears out this conclusion and shows how a tie between two previously separated systems may introduce a new region of instability unless the tie line has considerable damping.

Figure 5 is for two identical systems with identical governing mechanisms. Figure 6 is included to show the effect of having all the governing effort on one of the systems, with, however, the same effective speed regulation on the combined systems. It is seen that the system is slightly less stable when the governing is not uniformly distributed.

When the connected systems are not identical, physical considerations, as well as the equations given in the appendix, show that the normal modes of oscillation involve both the oscillation of one system against the other and also the oscillation of the combined system at frequencies determined by the system, tie-line, and governor characteristics. Thus when the system becomes unstable, both a tie-line power swing and also a swing of the average system frequency will in general occur simultaneously. The principal component of the tie-line swings usually has a period of from 0.5 to 5 seconds while the swing of average frequency may have a period of from 5 to 60 seconds.

Figure 6. Two interconnected systems

Effect of distribution of governing effort on stability. (Compare with figure 5)



Dead Band

In addition to the instability or hunting which may arise because of the characteristics of the governing mechanism as discussed in the previous sections, another source of hunting or undue frequency variations lies in mechanical imperfections and friction in the mechanism. These effects manifest themselves as a "dead band," or a frequency band within which the governing system will not respond.* There are at least three aspects of system performance which the dead band may affect:

(*a*). Accuracy of load division among paralleled machines,

(*b*). Response to the small frequency variations encountered on large systems,

(*c*). Possible excitation of sustained frequency or tie-line power oscillations.

(*a*). It is shown in the appendix that the possible inaccuracy of load division between two machines for a given total load is approximately equal to the ratio of the sum of the dead bands of the governing mechanisms of the two machines to the sum of their regulations. ($\Delta T = (e_1+e_2)/(R_1+R_2)$.) Since the kilowatt load error is equal and opposite on the two machines, the maximum percentage error evidently occurs on the smaller machine and may in the limit equal the ratio of the sum of the dead bands to the per cent regulation (on its own base) of the small machine. On the other hand, if frequency, rather than total load is maintained constant, the maximum load variation of any machine is equal to the ratio of its dead band to its regulation.

(*b*). Maximum frequency variations on large systems may be of the order of only 0.1 cycle per second, or about 0.2 per cent. It is thus evident that a governing mechanism having a dead band of 0.1 per cent might give a much smaller response to a frequency change than would be computed on the basis of its incremental regulation neglecting dead band. It is further evident that a reduction in dead band may well lead to a greater gain in the magnitude of the response than a reduc-

tion in incremental regulation. Moreover, a smaller incremental regulation would have the detrimental effects of reducing accuracy of load division for a given dead band and possibly increasing the frequency variations excited by dead band, while a smaller dead band would have just the opposite effects.

(*c*). The excitation of frequency variations by governor dead band has been studied by setting up the relations derived in the appendix on the differential analyzer of the Moore School of Electrical Engineering, University of Pennsylvania. The results were obtained as curves of frequency, tie-line power, etc., as functions of time, and of frequency versus turbine power input, following a sudden load torque change. The curves were continued long enough to observe the rate and manner of decay of the consequent oscillations, and to determine the magnitude of any sustained oscillation. Figure 13 shows a typical frequency versus time and frequency versus turbine input curve. A few of these curves have been included in the paper, and the principal results are summarized in figures 7–9 and 11–17 inclusive and in the tables.

SINGLE MACHINE

Figures 7–9 show the magnitudes of sustained frequency oscillations excited by governor dead band for the simple system considered in the first section of this discussion. Figure 7 includes the effects of dead bands of the first and second kinds described in the appendix, and shows that (*a*) for a governor with fast response the magnitude of the self-excited frequency oscillation is practically equal to the frequency change within which the governor may be insensitive, (*b*) the magnitude increases sharply as the border line of instability (see figure 3) is approached, and (*c*) the location of the dead band within the governing mechanism does not make very much difference.

Table I also gives information on the effect of location of dead band (first kind), and indicates some tendency for the effects to become greater as the location moves away from the governor head end of the mechanism and as the dead band is more evenly distributed. Of course, dead band cannot actually appear between the control output T_g and the turbine input T_g', since this is beyond the water or steam storage lag.

Figure 8, as compared with figure 7, shows the effect of load damping in suppressing the oscillations due to dead band of the first kind for sufficiently fast response. Figure 8 also shows the effect of a smaller regulation in requiring a much faster response for the same oscillation magnitude. For small time lag, dead band of the second kind is more severe, while for larger time lags dead band of the first kind is more severe.

Figure 9 shows the effect of an un-

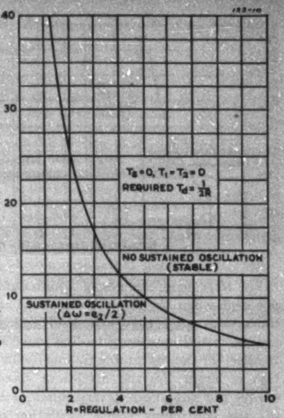

Figure 10. Required value of machine damping T_d to prevent self-excited oscillations

No governor time lags—dead band of second kind, e_2

damped synchronous tie between the machine of figure 7 and an infinitely large system.

Since hunting caused by dead band of the second kind was not suppressed by the load damping considered in figure 8, the amount of damping required to suppress such hunting was computed. Figure 10 shows the results of a calculation made for the most stable case of no time lag in the governing system. The required load damping coefficients are seen to be very large, so that one may expect that dead band of the second kind will always excite frequency oscillations.

Tests have indicated that dead band of the first kind is much more usual than dead band of the second kind, although perhaps neither kind may occur in a pure form. Therefore only the first kind will be considered in the discussion of interconnected systems.

INTERCONNECTED SYSTEMS

Figures 11 and 12 and tables II and III show some of the results obtained in the study of the performance of interconnected systems. The figures show the magnitudes of the sustained self-excited speed oscillations with different governor distributions. Note that a speed oscillation of 0.1 per cent with a period of about 2.1 seconds corresponds to a tie-line power swing of about 2.5 per cent or 25 per cent of the tie-line synchronizing power coefficient. The long period speed swings, however, have no corresponding power exchange, as the systems are then swinging more or less together. The principal self-excited speed oscillation occurred at the tie-line natural frequency in most of the cases studied, although in some cases the principal oscillation had a long period. Both the high- (tie-line) and low-frequency self-excited frequency oscillations may exist simultaneously, although as noted above there is a tendency for the high-frequency oscillations to predominate.

Figure 11 shows that for the case under consideration, if the governors on both systems have dead bands of 0.1 per cent, frequency and tie-line oscillations are excited over a definite range of time lags, but if the governor on one system has no dead band, and the governor on the other system has a dead band of 0.2 per cent, sustained oscillations are not excited.

Comparison of figures 11 and 12 shows that, as noted in figures 5 and 6, with all the governing on one of the systems, the combined system is slightly less stable than with a uniform distribution of governing.

In addition to stability, another aspect of system performance which might be affected by the distribution of governing effort over the system, is the transient swing following a sudden load change on one system. Figures 15 and 16 give information on this point. Figure 15 shows the frequency swings of two interconnected systems, following a load change of two per cent on one system. The upper set of curves is for similar governors of reasonably fast response, the middle set for a slow response governor on the system subjected to the load change, the lower set for a slow response governor on the other system. Figure 16 shows a similar set of frequency curves for a load change of eight per cent. Measurements taken from these curves and from other similar curves are summarized in table II.

It is seen that for load changes of about two per cent the relative speeds of response of the governors on two interconnected systems make very little difference in the maximum swing or continuing oscillations of the system speeds or tie-line load.

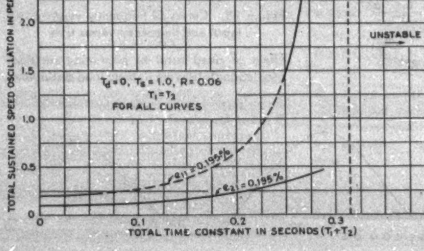

Figure 9. Self-excited speed oscillations produced by dead band

Effect of time lags of governing system—with system tie and no damping. (See figure 7 for definitions of e)

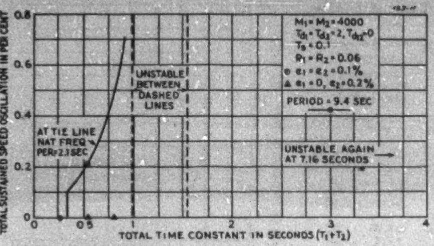

Figure 11. Self-excited system frequency oscillations in two interconnected systems

Effect of distribution of dead band and of time lags of governing system. e_1 and e_2 are dead bands (of first kind) on systems 1 and 2, respectively

For large load changes of about eight per cent when the faster governor is on the system subjected to the load change (*a*) the initial maximum tie-line swing is smaller, (*b*) the continuing tie-line oscillation is larger, (*c*) the maximum speed swings are not affected very much, and (*d*) the continuing speed oscillation is larger. With all the governing on the system subjected to the load change (*a*) the maximum tie-line swing is smaller, (*b*) the continuing tie-line load and speed oscillations are larger, and (*c*) the maximum speed swings are not appreciably different from the case of all governing on the other system. The maximum speed swings are in fact about the same as with the governing distributed over both systems.

Figure 17 shows the tie-line power swings following a load change on one system of an interconnection. The system parameters are different from those of figures 15 and 16. Table III is included to show for the case of figure 17 the effects on the rate of decay of tie-line oscillations, of governor response, dead band, and system and tie-line damping. It is seen from the figure and table that the effect of dead band is slightly to increase the effective time constant of the decay of the oscillations. That is, the component of oscillation which exceeds the dead band decays at about the same rate, but the rate of decay immediately changes to a very small value as soon as the oscillations become less than the dead band, so the result is a slightly smaller effective rate of decay. Doubling the regulation of the large system improves stability, i.e., increases the rate of decay (table III, run 61), while leaving the small system completely ungoverned except for its inherent self-regulation results in a slow decay (run 59). It is further shown that the initially assumed system damping must be increased by a factor of five to create the amount of damping contributed by the governors (run 62).

Summary of Results

Additional results not covered by the conclusions given at the beginning of the paper are as follows:

1. The stability of a system decreases if the speed regulation is made too small, except when the system consists of only one generator having a governor with droop compensation mechanism.

2. The magnitude of the sustained speed oscillations, if they exist, are at least equal to the width of the dead band of the unit having the smallest dead band, and become greater as the system characteristics approach the border line of stable and unstable operation. For dead band of the first or more usual kind, the speed oscillations will be damped out by load damping when the governing mechanisms are sufficiently stable (regulation sufficiently large or response sufficiently fast). Thus considerable information regarding probable system performance can be obtained from stability calculations made neglecting dead band. For units already installed the most effective way to improve undesirable system performance is to reduce the dead band or increase the speed regulation of the units known to be contributing to frequency instability.

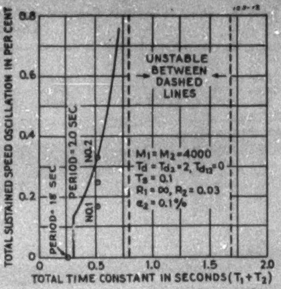

Figure 12. Self-excited system frequency oscillations in two interconnected systems

(Compare with figure 11 for effect of distribution of regulation and for definition of e_2)

3. The sustained frequency oscillations produced by dead band become somewhat greater as the location of the dead band moves from the input (governor head) toward the output (valve lift) end of the governing system. (See table I.) Distribution of a given total amount of dead band over the various stages of the governing system as compared to the same amount of dead band localized at one place in the mechanism increases the magnitude of the sustained oscillations. (See table I.) In spite of these variations, the over-all dead band of the governing mechanism of each prime mover, rather than that of any particular portion of the governing mechanism, is the principal significant factor in determining the magnitude of the frequency oscillations.

4. In analyzing a system, it is not proper to use a single effective dead band which is equal to some kind of average of the dead bands of the various governors on the systems. Instead, as the disturbance following a load change dies down, the governor having the smallest dead band tends to take

control and so produce a more stable condition. (See figure 11.) On the other hand, the average system regulation appears to be a reasonably good indication of the degree of stability, a uniform distribution of regulation being only slightly most stable. (See figures 5 and 6.)

5. For load changes of about two per cent or less, the relative speeds of response of the governing mechanism on two interconnected systems make very little difference in the maximum swing or continuing oscillations of the system speeds or tie-line load. (See figure 15.) Some differences appear when the load change is much larger, but it does not seem that similarity of rates of response is particularly significant for average load changes as long as no response is made so slow as to affect stability.

6. In case of two paralleled machines, dead band in the governors may cause a maximum possible error in load division which varies directly with the ratio of the sum of the dead bands to the sum of the speed regulations of the two machines.

Appendix. Explanation of System Quantities Used

Single System

The frequency variations of an electric power system may be studied by means of the following approximate torque equation.

$$(Mp+T_d)p\delta+T_g'=\Delta T \tag{1}$$

where

M is the effective inertia of the system, and is numerically equal to the starting time, i.e., to the time in radians required to come to full speed from standstill with rated torque applied. In terms of the conventional inertia constant *H* used in system stability studies, $M=4\pi fH$, where f is normal system frequency in cycles per second

T_d is the load damping characteristic, or slope of the combined prime-mover and load torque versus speed curves. That is, with fixed valve, the turbine torque T_t decreases with increasing speed, therefore $\partial T_t/\partial\omega=-1$ at full load while the electrical load torque T_e may either increase or decrease depending on the character of the load and on the degree of voltage regulation during the speed swings. Then $T_d=\partial T_e/\partial\omega-\partial T_t/\partial\omega$, where $\omega=p\delta$

For example, if the system kilowatt load is directly proportional to frequency $\partial T_e/\partial\omega=0$ which results in a value of $T_d=1$.

T_g' is the change in prime-mover output torque caused by motion of the control valves

ΔT represents the load changes to which the system is subjected. Only a unit function load torque change was used in the present study

$p\delta$ is the system speed or frequency, so δ is the effective system angle

$p=d/dt$

t = time in radians; 1 second = 377 radians for a 60-cycle system

All system torques and speed are expressed in per cent of rated torque and speed respectively throughout the paper.

The governing system, including the lags due to steam or water storage, was repre-

sented by a two-stage amplifier, each stage having a simple first-order time delay. That is, it was assumed that the speed change actuated some intermediate member Q, so that if there was an abrupt (unit-function) change of speed, Q would respond by approaching its final position along an exponential curve. Similarly, if Q changed abruptly, the prime-mover input T_g would respond by approaching its final position along an exponential curve. Such a governing system can be completely specified by two time constants T_1 and T_2, and an effective speed regulation R, where R is the steady-state incremental regulation defined as the ratio of per cent speed change to per cent power input change for a small change from 100 per cent speed. Thus the governor equations are:

$$\left.\begin{aligned} Q &= \frac{1}{T_1p+1}(p\delta)' \\ T_g &= \frac{1}{R(T_2p+1)}Q' \end{aligned}\right\} \qquad (2)$$

where

$p\delta'=p\delta$ as modified by dead band
$Q'=Q$ as modified by dead band
$T_g'=T_g$ as modified by dead band

The time constants T_1 and T_2 are expressed in radians, except in the figure titles, where they are in seconds.

The form of equations 2 may be shown to be appropriate for at least one component of a governing system by considering the case of a hydraulic relay. Here the piston speed px_3 may be approximately taken as proportional to the pilot valve lift x_2, or $px_3=kx_2$.

Further, the pilot valve lift x_2 is the resultant of the initiating displacement x_1 (e.g., of the governor head) and the restoring displacement x_3 of the piston, both acting through a floating lever. Thus, $x_2=lx_1-mx_3$ where l and m are constants.

Combining these two equations, the result is

$$px_3=klx_1-kmx_3$$

or,

$$px_3+kmx_3=klx_1$$

or,

$$x_3=\frac{(l/m)}{\left(\dfrac{p}{km}+1\right)}\,x_1$$

which is of the same form as equations 2.

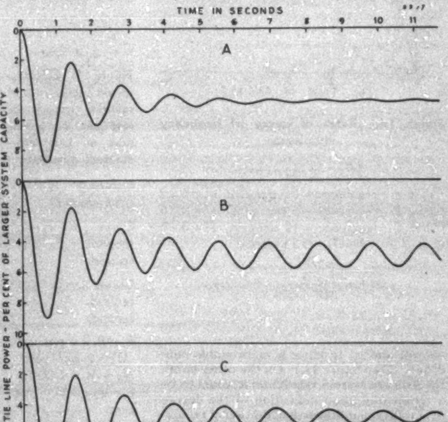

Figure 17. Decay of tie-line power oscillation as affected by dead band and tie-line damping

Dead Band

To represent approximately the effects of sticking friction, loose mechanical connections, pilot valve lap, or any other governor characteristic which might contribute to insensitivity, it was assumed that the governing system did not respond accurately to the true speed variations, but instead responded to some modified "speed" which lags the true speed. Two kinds of these dead bands were studied, as shown below:

First Kind

The first kind of dead band is illustrated in figure 18. As the speed ω increases, no effect is felt by the governing system until the speed arrives at the upper edge of the dead band (point a). From this point on the apparent speed ω', to which the governing system responds, is less than the actual speed ω by an amount depending on the original position in the dead band. For example, if the governor was originally in the middle of the dead band the speed error would be $e_{11}/2$. As soon as the speed ω starts to decrease at point b, the governing system is again in its dead band so the apparent speed ω' remains constant at its maximum value until the lower edge of the dead band is reached at point c. Operation then continues as indicated by figure 18.

Second Kind

The second kind of dead band is illustrated in figure 19. As the speed ω increases no effect is felt by the governing system until the speed arrives at the upper edge of the dead band (point a). At this point the apparent speed ω' suddenly jumps up to equal ω and remains equal as long as ω continues to change in the same direction. When the speed starts to decrease, at point b, the apparent speed again sticks at its maximum value until the speed error is

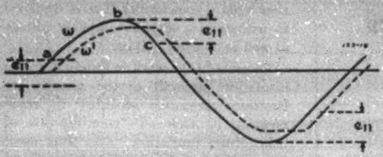

Figure 18 (left). Dead band of first kind

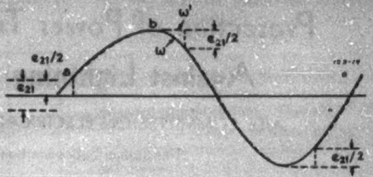

Figure 19. Dead band of second kind

half the defined dead band e_{11}, at point *c*. At this point the apparent speed again jumps down to equal ω, and operation continues as shown by the figure.

The first kind of dead band may represent for example a slack in certain parts of the mechanism, or a constant sticking friction force. The second kind might represent a sticking friction which breaks loose and becomes zero when the applied force (or speed error) is sufficiently large. It is evident that both of these kinds of dead band may also be applied at the intermediate point Q of the governing system, or at the prime-mover input T_g. These locations may be assumed to correspond roughly to particular locations in the actual governing system, from the input (governor head) to the output (control valve).

Two Interconnected Systems

For the case of two power systems connected by a tie line, if the inertia and governor characteristics of each system are considered as those of a single machine, the following approximate torque equations may be written.

$$\left.\begin{aligned}&(M_1p^2+(T_{d12}+T_{d1})p+T_s)\delta_1-\\&\qquad(T_{d12}p+T_s)\delta_2+T_{g1}=\Delta T_1\\&(M_2p^2+(T_{d12}+T_{d2})p+T_s)\delta_2-\\&\qquad(T_{d12}p+T_s)\delta_1+T_{g2}=\Delta T_2\end{aligned}\right\}(3)$$

where

T_{d12} is the tie-line damping torque coefficient, or change in the tie-line torque per unit change in relative system speeds, which depends on the strength of the tie and on the rotor electrical damping of the machines

T_s is the synchronizing torque coefficient, or change in torque per radian change in relative angle, between the two systems connected by the tie line

Subscripts 1 and 2 refer to the two systems 1 and 2 respectively.

The response characteristics of the governing systems are represented, as before, by two time delays between the initiating speed change and the resulting change in input torque.

$$\left.\begin{aligned}Q_1&=\frac{1}{(T_{11}p+1)}(p\delta_1)'\\T_{g1}&=\frac{1}{R_1(T_{21}p+1)}Q_1'\end{aligned}\right\}\qquad(4)$$

$$\left.\begin{aligned}Q_2&=\frac{1}{(T_{12}p+1)}(p\delta_2)'\\T_{g2}&=\frac{1}{R_2(T_{22}p+1)}Q_2'\end{aligned}\right\}\qquad(5)$$

where

T_{11}, T_{21}, T_{12}, T_{22} are the time constants of the two governing systems

R_1, R_2 are the speed regulations

Note that R_1, R_2 must be specified on the same kilovolt-ampere base, and so are not always equal to the conventional per cent regulations.

Dead bands of the first kind, of magnitude e_1 and e_2, were used between $p\delta_1$ and $p\delta_1'$ and between $p\delta_2$ and $p\delta_2'$ respectively, in the study of the two interconnected systems. To study the effects of dead band and the transient response of the system, equations 1 and 2, and 3, 4, and 5 were set up on the differential analyzer of the University of Pennsylvania, and the transient performance for a sudden load change ΔT_1 was determined for the cases discussed in the body of the paper.

Dead band of the first kind was simply represented by introducing a definite amount of backlash in the shaft connecting $(p\delta)'$ to $(p\delta)$, Q' to Q, or T_g' to T_g. Dead band of the second kind was represented by disconnecting $p\delta'$ from $p\delta$ until $p\delta$ reached its prescribed value, then (*a*) stopping the time shaft, (*b*) reconnecting $p\delta'$ to $p\delta$, and (*c*) setting the integrand $p\delta'$ to equal $p\delta$. The time shaft was then operated until $p\delta$ reached a maximum or minimum as explained in figure 19, when $p\delta_1'$ was again disconnected. Q' and T_g' were obtained in a similar manner.

To determine the limits of stable operation without dead band, the characteristic determinants of the coefficients of δ_1 and δ_2 in the equations were tested by Routh's stability criterion[9] over the range of parameters shown in the curves, an unstable system being defined as one in which transient oscillations will not die out.

Accuracy of Load Division

In equations 3, 4, 5 in the steady-state, $p\delta_1=p\delta_2=\omega$ and $\delta_1-\delta_2=\delta_{12}$. If dead bands e_1 and e_2 (of the first kind, on systems 1 and 2 respectively) are included, these equations become:

$$\left.\begin{aligned}T_{d1}\omega+\frac{\omega\pm e_1}{R_1}+T_s\delta_{12}&=\Delta T_1\\T_{d2}\omega+\frac{\omega\pm e_2}{R_2}-T_s\delta_{12}&=\Delta T_2\end{aligned}\right\}\qquad(6)$$

Adding the two equations 6 and solving for system frequency ω for the case of steady load, $\Delta T_1+\Delta T_2=0$, we obtain as the possible speed error,

$$\Delta\omega=\frac{\mp\frac{e_1}{R_1}\mp\frac{e_2}{R_2}}{T_{d1}+T_{d2}+\frac{1}{R_1}+\frac{1}{R_2}}\leqq$$

$$\frac{\frac{e_1}{R_1}+\frac{e_2}{R_2}}{T_{d1}+T_{d2}+\frac{1}{R_1}+\frac{1}{R_2}}\cong\frac{R_2e_1+R_1e_2}{R_1+R_2}\qquad(7)$$

and the possible torque variation of either machine is approximately (neglecting the small effect of T_{d1} and T_{d2}):

$$\Delta(\Delta T)=\frac{\Delta\omega\pm e_1}{R_1}=-\frac{\Delta\omega\pm e_2}{R_2}\leqq\frac{e_1+e_2}{R_1+R_2}\qquad(8)$$

If R_1, R_2 are taken as the per cent regulations on the bases of the individual machines, and if the fractions of the total capacity in machines 1 and 2 are K_1, K_2, then the per cent error of machine 1 is:

$$\Delta(\Delta T)\leqq\left(\frac{e_1+e_2}{\frac{R_1}{K_1}+\frac{R_2}{K_2}}\right)\frac{1}{K_1}\qquad(9)$$

Protection of Power Transformers Against Lightning Surges

AIEE COMMITTEE ON ELECTRICAL MACHINERY

Transformer Subcommittee*

Synopsis: This report presents a brief history of the subject of protection of power transformers against lightning overvoltages. The nature and magnitude of these overvoltages are described pointing out which ones are the most dangerous to apparatus.

The impulse voltage characteristics of transformers are given including volt-time curves, effects of (*a*) steepness of applied wave, (*b*) polarity of wave, and (*c*) mechanical deterioration of insulation in old transformers.

Similarly, impulse voltage characteristics of lightning arresters, rod gaps, and protector tubes are shown, thereby enabling the user to intelligently apply these devices for the protection of transformers.

The question of how to obtain various degrees of protection is fully discussed, ranging from the most effective protection to partial protection by using one or more of the following schemes:

(*a*). Direct-stroke protection and lightning arresters installed.

(*b*). Lightning arresters installed but direct-stroke protection omitted.

(*c*). Direct-stroke protection and station gaps installed, but lightning arresters omitted.

(*d*). Station gaps installed with neither direct-stroke protection nor lightning arresters.

Finally the proper selection of surge protective devices is discussed for the purpose of enabling the user to select the protective scheme that best suits his requirements.

A. General

As a result of the large amount of interest which has developed concerning the problem of protecting power transformers from overvoltages, the transformer subcommittee is presenting here a discussion of the problem in the hope that it will greatly clarify many points which have been given serious consideration in the past, and on which it is believed there have been, and still are, some different viewpoints. By discussing the fundamentals of transformer protection against overvoltage and some of the general controlling factors, a much clearer picture may be obtained of the degree of protection obtainable for transformers including both present-day designs and those built in the not too distant past.

Prior to some 15 years ago, insulation was built into a transformer largely on a 60-cycle basis. In general, sufficient was known at that time about 60-cycle characteristics of the insulation in a transformer to design it to withstand the double rating plus 1,000 specified test voltage, and to give satisfactory operation in service when subject to overvoltages such as normally encountered under operating conditions, exclusive of lightning. When, however, a large number of transformers put into use were subject to lightning conditions about which little was then known either as to magnitude of the lightning or the ability of the transformer insulation to withstand it, it was found that fundamental research on both of these problems was required before real progress could be made.

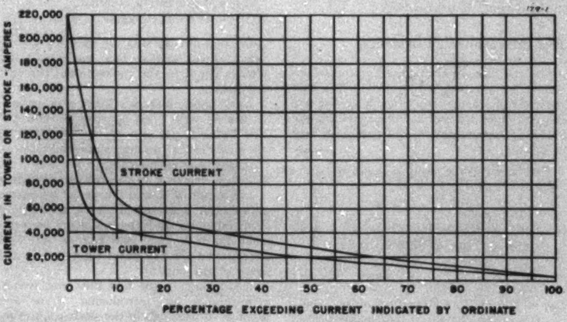

Figure 1. Lightning stroke and tower currents taken from reference 3

Without going into the details of the work done, it is a fact today that results of this research work have made available much data on the magnitude of lightning voltages to which transformers may be subjected in service and also correlated data on lightning or impulse strength of transformer insulation. As now built a transformer thus is designed to withstand a specified impulse voltage as well as 60-cycle voltage.

Progress of the work in building up the insulation strength of the transformer has been previously recorded[1] in which mention is made of "co-ordination of transformer insulation." As thus used, the word "co-ordination" has been used to mean protection of insulation rather than according to its more rigid definition of "having the same or equal" insulation as compared with some other device.

By co-ordination of transformer insulation, what is ordinarily meant is to build into the transformer, both on a 60-cycle and impulse basis, sufficient insulation so that the transformer will not be overstressed due to lightning when protected by readily available, protective devices, suitable for use with such transformers. As a step in this work of insulation co-ordination, there have been set up voltage test values or standards in the recognized preferred voltage ratings to which transformers in particular must conform as a matter of standardization. Standard basic insulation levels have been approved and submitted to the industry January 1941, by the joint committee on co-ordination of insulation of the AIEE, EEI, and NEMA. These levels are in reasonable conformity with the AIEE recommended impulse test values presented in June 1937, and have been recommended for use in place of those now appearing in the Proposed ASA Transformer Standards of 1940.

The problem of protecting transformers against overvoltages requires consideration of several factors. Among these are the following:

1. Magnitude and nature of system overvoltages.
2. Impulse or lightning strength of new and old transformers.

Paper 41-79, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 14, 1940; made available for preprinting December 21, 1941.

3. Voltage characteristics of protective devices.

4. Lightning voltages which may reach the transformer.

These are discussed in some detail under *B*.

B. Factors to Be Considered in Protecting Transformer Insulation

1. Magnitude and Nature of System Overvoltages

In analyzing the voltage to which a transformer may be subjected, there are several types of overvoltages to be considered resulting from the following causes:

(*a*). Generator overspeed (hydro).

(*b*). System switching.

(*c*). Arcing ground faults.

(*d*). Circuit harmonics.

(*e*). Lightning.

(*a*)—*Generator Overspeed Voltage* (*Hydro*). So far as "runaway voltage" is concerned, it appears that the system overvoltage will rarely, if ever, exceed twice normal before governor action takes effect to promptly bring the voltage back to normal limits. Where governor action is more sensitive, the double voltage value may not even be reached. Under these conditions, the resultant overvoltage is one of normal frequency and as a matter of both theory and practice, it appears that the usual applied or induced voltage tests are adequate to insure satisfactory insulation to take care of this situation.

(*b*)—*System Switching Surges.* The overvoltages which may appear on the transformer as a result of system switching surges have been quite thoroughly investigated in the past, particularly by field tests. These rarely exceed 5.5 times normal line-to-ground voltage, and only a very small per cent (2.5 per cent or so) exceed 4.5 times normal. These higher switching surges are of short-time duration and of a high frequency and therefore less severe than normal frequency voltages of the same magnitude. It appears as a practical matter that transformers built to withstand regular 60-cycle double voltage tests and the proposed impulse tests can safely withstand switching surges of the order mentioned above. The relative frequency of occurrence of such switching surges as shown[3] by extensive field measurements is given in figure 2.

(*c*)—*Arcing Ground Fault Voltages.* There are overvoltages[5,6,7] of a character simulating normal frequency voltages that may reach the transformer as a result of fault conditions. These range in the general order of 2.5 times the normal line-to-neutral voltage of the system. These voltages are practically nonexistent and of little or no concern in a solidly grounded-neutral system. They also appear to be adequately taken care of on an ungrounded system by equipment built with insulation designed for the 2×line-to-line voltage+1,000 volts standard as has been used for some time.

(*d*)—*Circuit Harmonics.* With certain relations between direct and quadrature reactances, particularly with salient-pole generators, single-phase faults create large distortions in voltage wave form. In conjunction with line capacitance, crest voltages several times normal are possible. Other sources of harmonic overvoltages[25] may also exist.

(*e*)—*Lightning Overvoltages.* The principal overvoltages which cannot be predicted with engineering accuracy as to magnitude or characteristics if no protection or limitations are applied, are the lightning voltages. The magnitude of such voltages is indicated in times line-to neutral voltage of the system in the upper curve of figure 2. The ability of transformer insulation in oil to withstand lightning surges is essentially independent of the polarity of the voltage, that is, positive or negative, but is known to depend on the rate of rise of the lightning voltage, its magnitude, and duration. Further, transformers may be subjected to overvoltages several times within one second or so as a result of a multiple or repetitive lightning stroke. The tower and stroke currents are indicated in figure 1.

From a consideration of overvoltages,

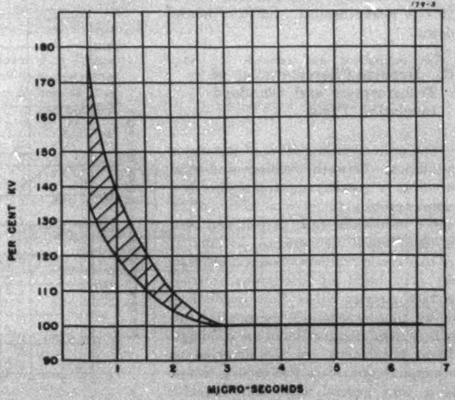

Figure 3. Volt-time curve of typical major insulation in transformers

Based on data in references 12 and 13

Table I. Standard Insulation Tests for Power Transformers

8.66	5.0	5.0	8.66	26	110	1.8	95
15.0	8.66	15.0	15.0	34	130	2.0	110
23.0	14.4	25.0	25.0	51	175	3.0	150
34.5	19.9	34.5	34.5	70	230	3.0	200
46.0	26.6	46.0	46.0	93	290	3.0	250
69.0	39.8	69.0	69.0	139	400	3.0	350
92.0	53.1	92.0	92.0	185	520	3.0	450
115.0	66.4	115.0	115.0	231	630	3.0	550
138.0	79.7	138.0	138.0	277	750	3.0	650
161.0	93.0	161.0	161.0	323	865	3.0	750
196.0	113.0	196.0	196.0	393	1,035	3.0	900
230.0	133.0	230.0	230.0	461	1,210	3.0	1,050
287.0	166.0	287.0	287.0	576	1,405	3.0	1,300
345.0	199.0	345.0	345.0	691	1,785	3.0	1,550

it should be apparent that transformers built in recent years apparently have sufficient insulation to withstand system runaway voltages, switching surges, harmonic voltages, and arcing ground voltages, without extensive and perhaps without any voltage limiting devices, but in the case of lightning voltages some protection must be provided to the transformer insulation if destructive impulse voltages and consequent failures are to be avoided to the greatest possible degree.

Knowing the relative magnitude and characteristics of the overvoltage conditions to which transformer insulation may be subjected, the next step is to discuss the characteristics of the insulation strength of the transformer itself and of the available protective devices, and finally the methods of limiting these voltages and providing reasonable margins to insure against insulation breakdown.

C. Impulse Characteristics of Transformers and Standard Insulation Tests

The protection in service of the major insulations (between windings and from windings to ground) in a transformer is a simpler problem than the protection of the minor insulations (coil to coil and turn to turn) which are subjected to internal voltage concentrations. Some transformers may build up dangerous internal voltage stresses either from oscillations or by concentration of the applied impulse in a limited portion of the windings. These phenomena are too involved to attempt treatment in this report, except in a very general way. The impulse voltage to which the major insulation is subjected can be fairly well controlled by protective devices external to the transformer. On the other hand, for a given level and type of protection the internal stresses set up in minor insulation depend on the steepness of the front and length of the incoming waves, the constants of the transformer circuit, and the type of construction used in the transformer.

It is assumed here that both major and minor insulations in modern transformers are well balanced under any condition. But for older transformers an internal (minor) insulation failure may be caused by a lower applied voltage than required to cause failure of the major insulation, especially for steep front waves which overstress the insulation between the line end coils and turns. It is also assumed that manufacturers when providing volt-time curves for existing transformers will take the minor insulations into consideration.

Table I shows the standard insulation tests for power transformers, modified to be in agreement with the new standard basic impulse insulation levels, but otherwise similar to that in the Proposed American Standards for Transformers, Regulators, and Reactors, published by the American Standards Association.

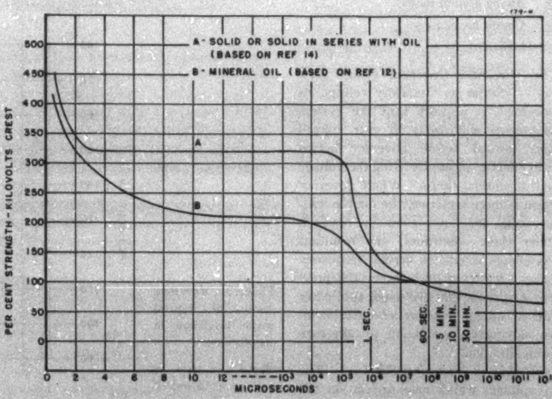
INSULATION STRENGTH OF TRANSFORMERS

Low-Frequency Strength. So far as withstanding surge voltages is concerned the low-frequency strength of a transformer is a rough measure of the impulse strength of the major insulation only. Induced voltage tests demonstrate to some extent the impulse strength between coils (but not between turns) for the slower waves, but do not indicate the strength for steep front waves which impose high stresses between line end coils. The principal value of standard low-frequency tests is in detecting faults due to possible errors in design, material, and workmanship.

VOLT-TIME CURVE OF MAJOR INSULATION

Laboratory tests[4,10,11,12,13] have indicated that the impulse strength, as shown on a volt-time curve of typical major insulation for transformers, decreases with time to approximately three microseconds and remains approximately constant for times longer than this as shown in figure

Figure 4. Typical volt-time curves of insulation



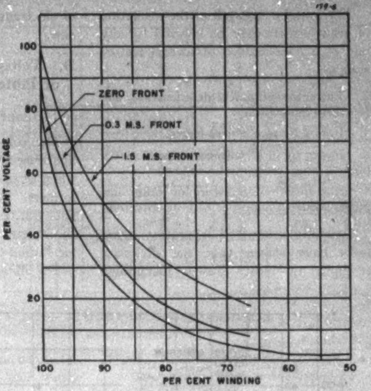
3. In other words, the failure voltage decreases with the "time" from zero to approximately three microseconds and then remains constant up to 50,000 to 75,000 microseconds as shown in figure 4. It then decreases again (during various times of exposure to normal or low-frequency voltage) and tends to flatten out for long periods of time.

The shape of the volt-time curve for oil alone, figure 4, is somewhat different from the curve for insulation mentioned above, the breakdown voltage decreasing from near zero to eight to ten microseconds, remaining approximately constant down to about 1,000 microseconds, then decreasing again and flattening out at approximately one minute time.

The volt-time curve of the breakdown of solid insulation and oil in series is essentially of the same shape as that for solid insulation alone. Where the failure of major insulation in the vital parts of a transformer, having some solid insulation in series with oil, would take place by puncture, the volt-time curve of "solid insulation" can be used for co-ordination purposes. It is recognized, however, that where failure would be by creepage, the volt-time curve may approach that for oil alone.

The "over-all" volt-time curve of a transformer takes into account the volt-time curve of its bushings, as well as the windings. If the long wave flashover of the bushing is higher than the impulse level (demonstrated or estimated strength) of the windings, the volt-time curve to be used for co-ordination purposes can be that of the windings. On the other hand, if the long wave flashover of the bushing is less, then in order to prevent bushing flashover (and consequent service interruption) on long waves, the volt-time curve to be used for protection purposes should be a composite curve of bushing and winding as shown in figure 5.

Figure 6. Effect of wave front on initial voltage distribution in some types of windings



Initial Impulse Voltage Distribution as Affected by Steepness of Applied Wave

The effect of impulse waves applied to transformers which are not designed to produce an approximate uniform voltage distribution differs considerably with the type of winding and the method of insulation of the transformer winding. Concentration of the stresses within the windings varies depending (*a*) on the construction, and (*b*) on the steepness of the applied wave. The effect of the steepness of the applied wave on the initial voltage distribution on some transformer constructions is illustrated in figure 6.

Effect of Polarity of Wave on Transformer Strength

So far as the winding in oil is concerned, the impulse strength is the same for both positive and negative waves. The only way in which the effect of polarity must be taken into consideration in operation is in its effect on the level of the protective device used. Lightning arresters, however, are not affected by polarity but most air gaps, such as rod gaps, bushings, and insulators have higher critical (1.5x 40) flashover for negative waves although the effect of polarity tends to disappear for steep front waves. Therefore, when depending on air gaps alone for partial protection, as discussed later, the effect of polarity should be considered, remembering that the majority of lightning voltages recorded in service are of negative polarity.

Effect of Age on the Impulse Strength of Transformers

The question of the effect of age on the impulse strength of transformers has often been raised.

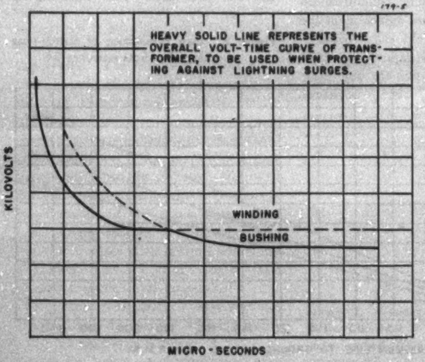


Figure 5. Typical volt-time curve of transformer winding and bushings

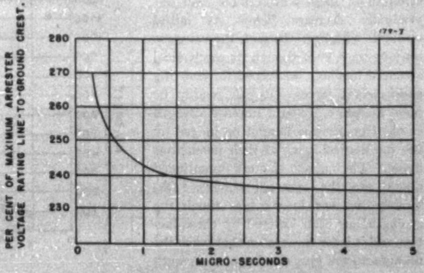
Figure 7. Arrester gap breakdown, tolerance ±20 per cent

Taken from reference 24



The impulse strength of the insulation of transformers may be lowered by any one or a combination of several factors such as:

1. Extreme mechanical deterioration, due to excess temperature.
2. Injury by mechanical forces.
3. Injury by surge voltages not sufficiently high to cause complete breakdown.
4. Absorption of moisture or other impurities due to improper care in operation.

Carefully conducted laboratory aging tests have shown that the dielectric strength of most fibrous insulations showed a marked increase in dielectric strength at the start, owing to removal of the last traces of moisture. As the test continued the dielectric strength slowly decreased but did not fall below its initial strength until practically all its mechanical strength was gone; that is, until it became charred and cracked.

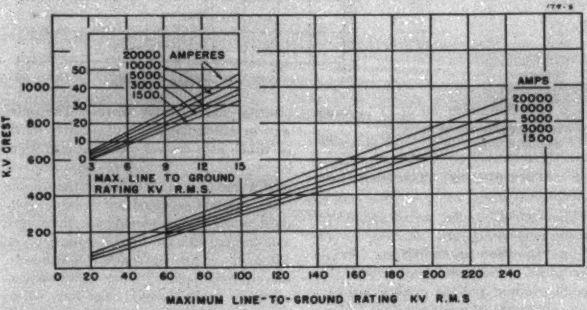


Figure 8. IR discharge voltage, 10–20 microsecond wave of station-type arrester

Tolerance ±15 per cent. Taken from reference 24

It is for this reason that, considered only from the standpoint of the mechanical aging of the insulation, the impulse strength of most transformers does not gradually decrease below its initial strength with age. In fact, the converse may be true, even though its mechanical strength has been weakened for resisting short-circuit forces. It can readily be seen, therefore, that the impulse strength of old transformers cannot be judged by the mechanical aging of their insulations alone. The other factors mentioned above are the controlling ones. Obviously, no one knows how much the strength has been lowered by these factors and it is for this reason that when the manufacturers give the impulse strength of old transformers it is based on "when new."

D. Voltage Characteristics of Protective Devices

(a). Lightning Arresters

The volt-time curve characteristics of lightning arresters should be considered when arresters are used to protect transformers. All arresters have relatively flat volt-time curves. Figure 7 shows the general shape of the volt-time curve for station-type arresters.

The impulse gap breakdown voltages and *IR* drop voltages of lightning arresters based on AIEE test conditions are given in figures 7 to 14 inclusive. The arrester performance is the same for either positive or negative impulses.

(b). Rod Gaps

Tentative volt-time curves for standard rod gaps for 1.5x40 negative waves are shown in figure 15. These curves, especially at short times, are subject to change when the subcommittee of the AIEE-EEI-NEMA joint committee on insulation co-ordination agrees upon the values to be used.

The curves given in figure 15 are the average of test data obtained up to the present time by the Ohio Brass, General Electric, and Westinghouse laboratories.

The 60-cycle and critical (50-50) impulse spark-over voltage of standard rod gaps are shown in figure 16. These curves (except the 60-cycle wet) are based on data agreed upon by the EEI-NEMA laboratory group.

(c). Protector Tubes

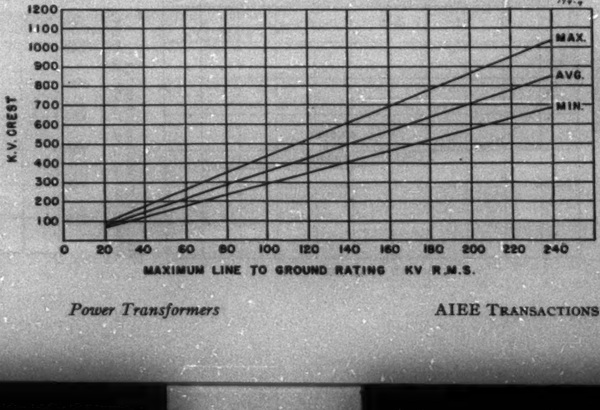
Typical approximate volt-time curves of protector tubes are shown in figure 17. These curves are shown in crosshatched section because the AIEE lightning arrester subcommittee has not yet published final values.

E. Methods of Protection Available

1. Interception of Direct Strokes

With the present knowledge of the characteristics of natural lightning it is possible to provide a means of intercepting direct strokes thereby preventing them from coming in contact with the phase conductors except in rare cases. This type of protection takes the form of shielding. The popular method of intercepting the lightning stroke is by means of a ground wire. The ground wire is placed above the object to be protected and the grounding resistance of this wire is kept low so that the potential of the ground wire or the supporting structure does not become high enough to cause a flashback from the steel to the phase conductor. The ground wire is placed over the substation or over the transmission line or both depending upon the degree of protection desired. Another method of intercepting the direct stroke is to erect a mast or a number of masts on the top of the substation steel to adequately shield the bus structures. This shielding by

Figure 9. Gap breakdown of station-type arresters, taken from reference 24



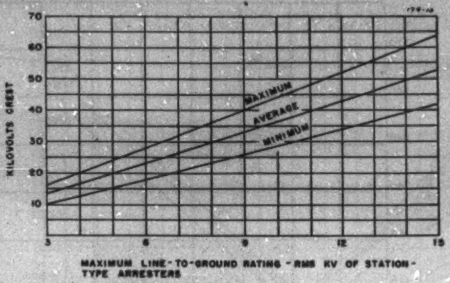


Figure 10. Gap breakdown based on AIEE wave, taken from reference 24

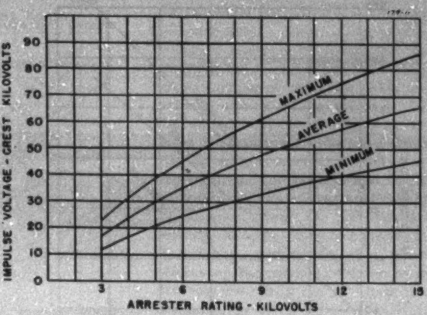

Figure 11. Gap breakdown voltages, line-type arresters, taken from reference 22

masts has in some cases been carried further and the masts have been erected entirely separate from the substation steel. This form of protection has been used where direct stroke protection is desired in connection with old substations or where equipment such as disconnects prevents erecting the masts on the top of the substation steel. Again the mast must be high enough to adequately shield the apparatus under consideration.

In applying any of the above arrangements the angle or area of shielding should be given careful consideration. Initially such shielding was based on a ratio of horizontal radius of area protected to vertical height of mast of two to one (64 degrees to vertical) or greater. The ratio has gradually decreased and recent studies have indicated that one to two may be desirable.

2. Lightning Discharge Devices

A. Lightning Arresters. The lightning arrester is the most generally used protective device as it not only discharges the surge current to offer apparatus protection but it also interrupts the flow of power follow current thereby protecting the service. The lightning arrester volt-time characteristics, as compared to those of transformers, make it ideally suited for this application. Its voltage characteristics are made lower than those of the insulation in the apparatus at long times and due to the arrester's relatively flat volt-time characteristic it provides a larger margin of protection at the short times. This margin is necessary in a number of cases when effects which are explained later of lead lengths and ground resistance are considered.

B. Plain Rod Gaps. Rod gaps are sometimes used in parallel with apparatus to act as discharge devices. A comparison of the volt-time characteristic of a gap compared to the volt-time characteristic of a lightning arrester will readily show that the rod gap is not fundamentally a good protective device because if it is selected to protect the apparatus at the long times it will not provide protection at the short times. On the other hand, if it is set to provide adequate protection at the short times the gap will be so short it will be susceptible to frequent flashovers due to switching transients and minor lightning surges. The practicable gap setting selected, therefore, is a compromise. The plain rod gap has been used in some instances as a primary protective device but it has been more commonly used as a supplemental device.

C. Fuse Gaps. Fuse gaps have the same characteristics as plain rod gaps except a fuse is placed in series to provide a means of interrupting the power follow current caused by flashover. This arrangement therefore gives the added feature of protection to service when compared to the plain rod gap. The maintenance and replacement of fuses are items for consideration in this form of protection.

D. Protector Tubes. The volt-time characteristics of protector tubes offer better protection than those of plain rod gaps but the impulse voltage does increase at the shorter times more rapidly than on a lightning arrester. The protector tube is designed to interrupt power follow current, and this therefore dictates the length of tube for a given voltage which in turn determines the impulse breakdown of the device. Where the system is solidly grounded the tube breakdown can be lower than on a free neutral system so that in the former case it serves as a very good secondary class protective device. It has been quite extensively used on a few towers close to a substation serving as a parallel discharge path to the lightning arrester discharge path.

E. Control Gap. The control gap has been used as a secondary protective device with and without fuses. Its volt-time characteristic is somewhat better than that of the equivalent rod gap but it still has some of the factors of the plain rod gap and is, therefore, classed with it when selecting protective devices.

3. Capacitance

When lightning strikes a line the substation voltage will rise at a rate determined not only by the original voltage on the line but also by the magnitude of capacitance in the substation. The effect

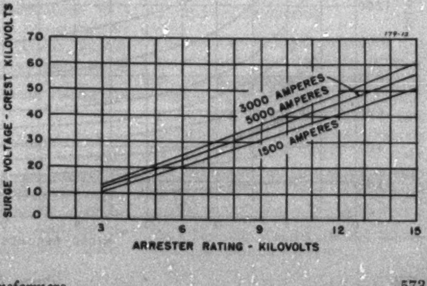

Figure 12. Average IR drop, line-type arresters, taken from reference 22

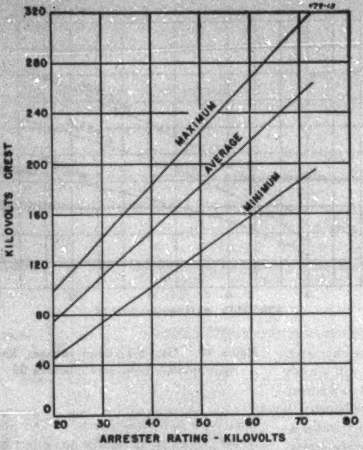

Figure 13. Gap breakdown voltages, line-type arrester

Taken from reference 23

of the station capacitance is to decrease the rate of voltage rise at the transformer and in some cases to reduce the voltage at the transformer. This inherent characteristic of substation equipment is more effective the further the stroke occurs from the substation as the rate of increase of voltage in the substation will be controlled to a greater extent if the capacitance is charged through the surge impedance of the line. If protective devices such as protector tubes are placed on the line the station capacitance will be more effective. However, if station capacitance were depended upon as a protective scheme, there would be no reliable protection. This would be particularly true for strokes occurring close to or directly on the substation.

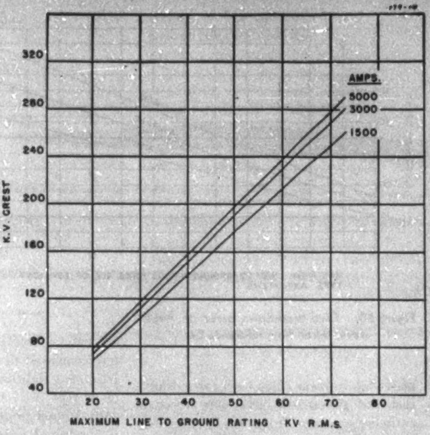

Figure 14. Average IR discharge voltage, line-type arresters, 10–20-microsecond wave

Taken from reference 23

F. Effect of Terminal Conditions

(a). Ground Resistance

The magnitude of ground resistance is very important in securing good protection, particularly where the protective device is not connected to a ground in com-

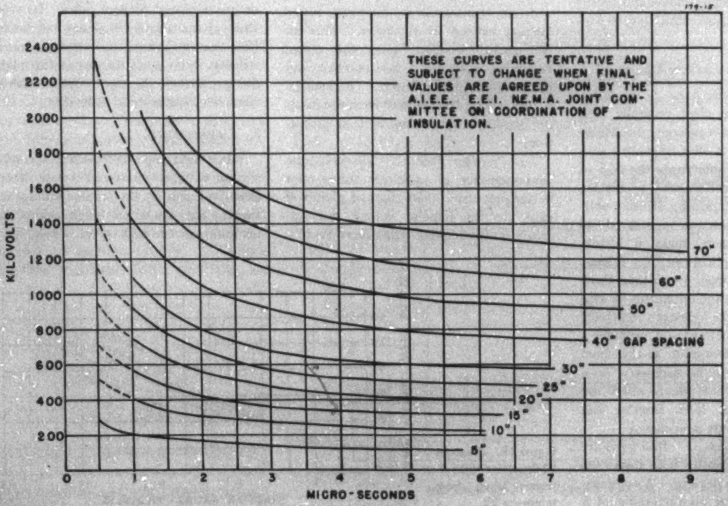

Figure 15. Volt-time curves of rod gaps under standard atmospheric conditions, 1.5x40 negative waves

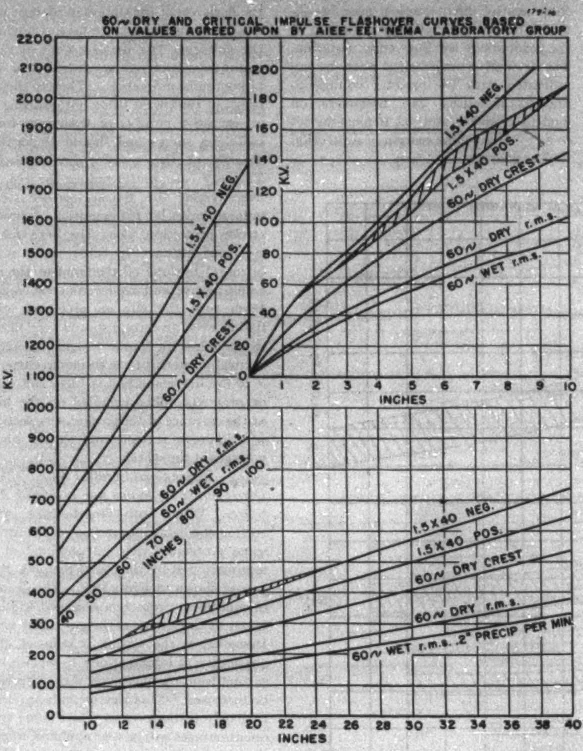

Figure 16. Spark-over voltage of standard rod gaps at AIEE standard atmospheric conditions

mon with the apparatus ground. In this case the resistance drop adds directly to the lightning arrester discharge voltage and this addition may be sufficient to cause flashover or failure of the apparatus to be protected. If the lightning arrester ground is connected to the apparatus ground then the apparatus tanks will rise in potential the same as the arrester ground so only the lightning arrester voltage will appear across the apparatus. This means, however, that although the apparatus so connected will be protected, the bus is subjected to higher voltages, the degree depending upon the distance from the lightning arrester installation. For this and other reasons it is considered good practice to keep the ground resistance of large stations below one ohm. In the outlying regions where a small transformer is the only equipment to be protected it may be economically necessary to let the ground resistance exceed one ohm. Soil conditions will determine the ground grid necessary to achieve the desired results.

(b). Capacitance

As previously discussed, the larger the inherent capacitance of the substation the more it becomes effective as a protective measure. The limitations to a scheme depending upon capacitance are such as to make its application limited. It should be considered as a reserve factor.

(c). Circuit Feet From Protective Device to Apparatus

The distance from the protective device to the apparatus to be protected is a very important factor, particularly for direct strokes and becomes of less importance the further the stroke originates from the substation. Considering the worst case of stroke originating close to the substation the rate of rise of voltage will then have a direct bearing on the voltage appearing at the equipment. In general it can be stated that the voltage at the equipment can reach twice the lightning arrester voltage as a limit. As the distance between the lightning arrester and apparatus is reduced, or as the rise of voltage is reduced, the voltage at the apparatus will approach that of the lightning arrester. It is essential to keep the distance between the protective device and the apparatus to be protected to a minimum, particularly when direct strokes are the criterion of design as in this case the rate of rise of voltage is a maximum.

G. Degrees of Protection

1. Direct-Stroke Protection and Lightning Arresters Installed

Based on present-day knowledge, the most effective protective setup consists, as illustrated by figures 18*A* and 18*B*, of lightning arresters supplemented by proper direct-stroke shielding of the station and overhead-ground wire protection extending approximately 2,500 feet or more from the station. Very careful design of overhead-ground wire arrangement is necessary if complete protection is desired, although it is well to realize that direct-stroke protection cannot necessarily be relied upon 100 per cent. If direct strokes are prevented in the space within the station and for a distance of approximately 2,500 feet from the station, the surge impedance of the line between the arrester and the nearest possible direct stroke will limit the discharge current at the arrester. Under these conditions, modern arresters having suitable performance characteristics and properly located will ordinarily limit the voltage to a value well below the insulation level of the modern transformer. For lines 46 kv and below, the installation of ground wires may not be economically justified.

2. Partial Protection

There may be installations such that the expected revenue and the nature of the load do not appear to justify the installation of the most effective protection. In this case, the user may prefer to take an additional risk of service interruption or apparatus failure, rather than make the expenditure necessary to install maximum protection. Three varieties of partial protection may be classified as:

(*a*). Lightning arresters installed but direct-stroke protection omitted.

(*b*). Direct-stroke protection and station gaps installed, but lightning arresters omitted.

(*c*). Station gaps installed with both direct-stroke protection and lightning arresters omitted.

(*a*)—*Lightning Arresters Installed but Direct-Stroke Protection Omitted.* For years it has been common practice to use lightning arresters without direct-stroke protection to protect power transformers and station apparatus on 15, 23, 34.5, and 46-kv systems. Modern arresters, if the line is not too highly insulated, should afford protection for modern transformers against waves of any rate of rise, originating more than about one-half mile from the station. This practice cannot be relied upon to give protection against direct strokes at or near the station. As shown in figure 18*C*, some protection from nearby direct strokes may be obtained by the installation of a rod gap at the point where the lines enter a station. The setting of such a gap must be coordinated with the arrester voltage to prevent undesired gap flashovers on moderate strokes and yet it must be set so as to afford some margin of protection to the apparatus.

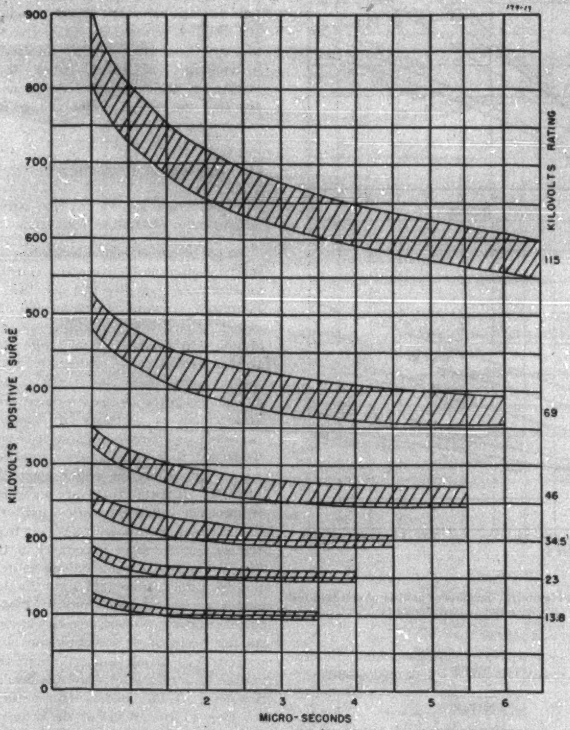

Figure 17. Approximate impulse characteristics of protector tubes

Some degree of direct-stroke protection will result if protector tubes or other protective devices are used for a distance of 2,500 feet out from the station, particularly if line insulation is high. Low-ground resistance for the tubes or interconnection to station ground is desirable for this application to prevent unpredictable voltages from reaching the station.

(*b*)—*Direct-Stroke Protection and Station Gaps Installed, but Lightning Arresters Omitted.* When direct-stroke protection is installed, but lightning arresters are omitted as shown in figure 18*d*, the station equipment may be stressed up to the flashover of the station insulation, unless some other means are taken to reduce the voltage. The use of plain rod gaps might be considered as a method of obtaining some protection. The gap should be set at the lowest value not resulting in an excessive number of flashovers from switching surges and should be located directly at the transformer terminals. The user can greatly reduce the risk of overstressing the transformer by steep voltage waves by the extension of direct-stroke protection along the lines for a sufficient distance (possibly three miles or more) to slope off the front of the incoming wave and reduce its crest value. Each time the gap or protector tube flashes over, an outage should very likely result unless the gap is designed to automatically interrupt the dynamic current.

If the line insulation is high, rod gaps or protector tubes installed on the line at the entrance of the ground-wire section will improve service and reduce surge voltages at the station.

(*c*)—*Station Gaps Installed With Neither Direct-Stroke Protection nor Lightning Arresters.* When both direct-stroke protection and lightning arresters are omitted some protection may be obtained at a minimum cost by the use of the plain rod gap as shown in figure 18*E*. The degree of equipment protection obtained will increase as the setting of the gap is reduced. However, as the setting is reduced, the possibility of interruptions to service resulting from the flashover of the gap will be increased. This scheme finds application only in those cases where more frequent outages will be tolerated and where the user is willing to accept increased risk of transformer failure.

3. SELECTION OF SURGE-PROTECTIVE-DEVICE RATING

The protective device should be selected and the scheme of protection devised so that under the conditions presumed to exist the protection level obtained will be below the insulation level of the transformer.

Protective devices have ratings based on the voltage at which they are designed to operate. In the case of lightning arresters, the rating is the maximum voltage at which power follow current will be interrupted. Protector tubes are rated both on voltage and power follow current magnitude. Rod gaps do not have any established voltage ratings.

The protected level provided by a lightning arrester is generally in direct proportion to its voltage rating, and it is therefore desirable to use as low a rating as practical. In order to do this it is necessary to know something of the magnitude of the dynamic voltages which may be impressed on the arrester under all conditions, including faults on the system. The magnitude of line-to-ground voltages under fault conditions depends largely on the effectiveness with which the neutral of the system is grounded and may be determined by the ratio of zero sequence impedance to positive sequence impedance at the point of application.

The practice has been to manufacture lightning arresters in ratings such that "full voltage" arresters with ratings slightly above line-to-line voltage are available for isolated or "not effectively grounded" neutral systems, and arresters of reduced voltage rating are available for systems with an "effectively grounded" neutral. This has been discussed in many Institute papers.

Reduced rated arresters may be used when applicable to give a greater margin of protection, or in the higher voltages may permit the use of the next lower insulation level on apparatus than would otherwise be used.

The protective devices such as arresters or protector tubes will be most effective when mounted directly on or adjacent to the transformer tank and with line and ground connections between protective device and transformer as short as possible. In large stations more than one set of protective devices may be necessary to keep the circuit-feet between protected apparatus and protective devices within acceptable limits.

Complete Analysis of Motor Temperature Rise

FREMONT FELIX
MEMBER AIEE

H. G. JUNGK
MEMBER AIEE

Synopsis: The present-day demand and imperative need for higher speeds and increased outputs in every phase of industry and transportation have emphasized the tremendous importance of realizing the maximum utilization of the service capacities built into electrically-driven equipments.

In a great majority of cases the predominant limitation in this direction lies in the heating capacity of the electric motors and this paper has been written to show a general method of "mapping" the heating performance of electric motors over their entire speed-torque operating range so that their maximum performance may be judiciously realized within their heating limitations.

Many excellent papers have described methods by which, starting from design constants and losses, the temperature rise of a machine can be calculated for a given load condition. Also some of the earlier papers[1] have brought out the fundamentally simple functions which govern the temperature rise of electrical machinery. In this paper, the authors show how, starting from the results of a small number of tests, it is possible to build up a complete temperature-rise map of the motor applicable to any conceivable speed and torque service condition.

This method was worked out in detail for the single-phase, commutator-type, traction motors which equip the modern a-c locomotives and the enlightened interest of the Pennsylvania Railroad led to the preparation by two electrical manufacturers of an unusually complete analysis of traction motor performance.

The original calculations, which were submitted in 1935 have been in continuous and successful use ever since, for the locomotives of the type shown in figure 1 and have been fully substantiated by later tests made on motors built on subsequent orders. The authors feel, therefore, fully confident, in recommending that a similar approach and method of plotting be applied to other applications in transportation or industry where widely varying load conditions are encountered and where it is important to secure the utmost utilization of a large number of similar motors.

Part I. Wide-Range Charting of Motor Temperatures

Performance Possibilities of Commutator-Type A-C Traction Motors

The performance of single-phase, commutator-type, locomotives is not limited to definite operating speeds as is the case with induction-motor locomotives, nor to fixed motor voltages as is the case with d-c locomotives, nor to a definite horsepower as is the case with internally powered locomotives.

The only boundaries which these single-phase locomotives recognize are those defined by the maximum permissible speed, the maximum tractive effort, and the top speed-tractive effort curve along which maximum horsepowers are developed. In addition, many of the high-speed passenger locomotives demonstrate their adaptability to different types of service by pulling freight trains weighing up to 5,500 tons at speeds between 30 and 50 miles per hour where operating points can be chosen, from many of the 60 available notches, as freely as in the 60-to-80 miles per hour passenger speed range.

With this wide operating range, with their continuous rated capacity of 4,620 horsepower, and their peak output of 8,500 horsepower, the single-phase locomotives of the Pennsylvania Railroad offer a concentration and an availability of power which has never been realized before. The performance capacity of these motive power units, at the same time very powerful and very finely controllable, should be known under all operating conditions in order that their possibilities may be realized to the utmost.

Traction-Motor Temperature Limitations

Although there are several links in the transformation of electrical energy into mechanical power to drive the wheels of the locomotive, the fact that the space limitations inherent in locomotive construction affect the traction motors more stringently than any other apparatus, and also the fact that the traction motor output is delivered over such a wide speed range, combine in restricting the input of electrical energy to the locomotive to the amount permitted by the commutating and heating capacity of the traction motors. Within the limits of commutation the traction motor heating capacity is the factor which determines the performance of the locomotive as a whole.

This paper explains the analysis by which the temperature rise is determined for any operating cycle, the criterion of a correct application being that the temperature of the windings as measured by their resistance must not exceed the permissible values set by the American standards for railway motors with class *B* insulation. The "normal" temperatures may be considered as the superposition of 120-degrees-centigrade rise for the armature or 130-degrees rise for the field above a 25-degrees-centigrade ambient. The "peak" temperatures may be considered as the same rises (120 degrees centigrade and 130 degrees centigrade) superimposed over a 40-degrees-centigrade ambient.

Temperatures	Normal (Degrees Centigrade)	Peak (Degrees Centigrade)
Armature	145	160
Field	155	170

Complete Mapping of Temperatures

The wide diversity of questions to be answered about the effect on temperature of time, speed, and tractive effort made it quite apparent that a very comprehensive and complete "map" of these relations had to be worked out. At first this appeared very difficult and complicated. However, the wide-range method to be described proved to give a most complete picture of the motor performance in a far shorter time than the partial methods previously used.

Charts of Temperature Rise

Figures 3*a* and *b* show, side by side, the two final charts from which the temperature rise is obtained for the armatures of the twin-armature traction motor shown in figure 2. Six of these twin-armature traction motors, that is, 12 armatures in all, equip the locomotives of the type shown in figure 1, of which more than 100 are in service on the electrified territory of the Pennsylvania Railroad.

Any chosen cycle of operation, including accelerations, overloads, high-speed running, coasting, or layover, can be accurately analyzed from the standpoint of the temperature rise of the armature. Similarly the charts on figure 4*a* and *b*

Paper 41-29, recommended by the AIEE committee on land transportation, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted October 30, 1940; made available for preprinting December 5, 1940.

Fremont Felix is in the industrial engineering department of the General Electric Company, Schenectady, N. Y. H. G. Jungk is a-c traction motor engineer of the Westinghouse Electric and Manufacturing Company at East Pittsburgh, Pa.

[1] For all numbered references, see list at end of paper.

Figure 1. 2-C-C-2, 11,000-volt, 25-cycle, 4,620-horsepower, single-phase locomotive in passenger service

Figure 2 (right). 25-cycle, 770-horsepower, twin-armature, single-phase traction motor

will give the corresponding information in regard to the temperature rise of the field.

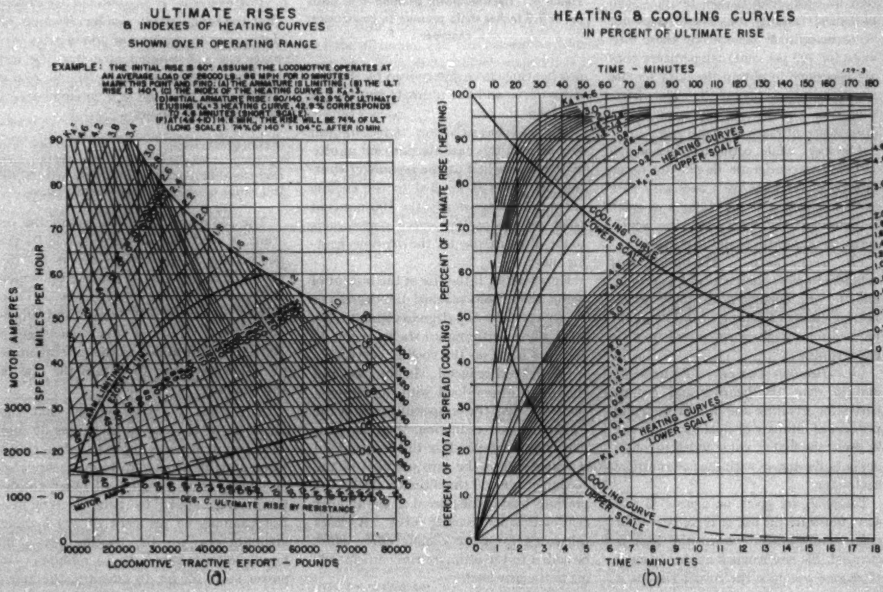
For low-speed operation, where the exciting field is shunted, the effect of speed on temperature rise is very small and, in this short range only, it proved practical to simplify the required charts by preparing curves 5*a* and *b* which are used as follows.

The abscissa of the initial rise (at the time the accelerating tractive effort is applied) gives the equivalent time which it would have taken to reach this temperature starting cold. Adding to this time the minutes of operation at the accelerating tractive effort and reading the corresponding ordinate gives the rise at the end of this period of acceleration.

The use of the charts on figures 3, 4, 5, and 6 will give in a few minutes the temperature data which would otherwise require hours of locomotive operation on test. This is specially suited for determining the tonnage which a locomotive can haul over any portion of the electrified profile.

(*1*). *Ultimate Rises.* Figures 3*a* and 4*a* show the final or ultimate rises which will obtain if any speed and tractive effort are maintained for a long pe-

Figure 3. Traction motor armature heating at 5.8 inches static pressure in commutator chamber



(a) (b)

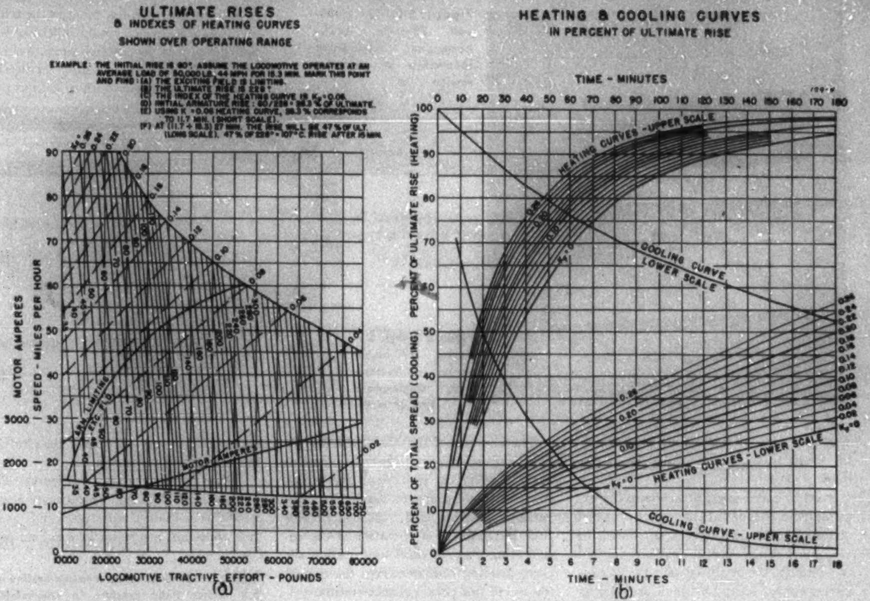


Figure 4. Traction-motor exciting-field heating at 5.8 inches static pressure in commutator chamber

riod of time, four to five hours. Such prolonged running, of course, does not occur in railroad service but these ultimate (or 100 per cent) temperature rises are necessary to obtain the data for the usual short-time operation. The short-time rises can then be expressed in per cent of the ultimate (or final) rise.

Likewise, while ultimate rises above 150 degrees centigrade should not occur in service, yet they are a necessary part of these charts and calculations in order to determine the short-time rises which occur on acceleration and overloads.

(2). *Index Lines.* The broken lines extending across the curves of figures 3*a* and 4*a* are numbered to show which heating curves of figures 3*b* and 4*b* are to be used for any given speed and tractive effort point.

(3). *Heating Curves.* Figures 3*b* and 4*b* show the heating and cooling curves for armature and field expressed in per cent of ultimate or final rise. As will be seen, the higher value index numbers apply to the curves with the faster rate of heating up.

Examples are given on figures 3*a* and 4*a* to illustrate the use of these curves for rising temperatures; when the load is changed, the rise reached at the moment of change becomes the initial rise on a new heating curve determined by the new index curve and the ultimate rise for the new load.

(4). *Cooling Curves.* (*A*). Power shut off: In this case the per cent of ultimate rise reached at the instant of shutting off power is applied to the cooling curve. In other words, the 100 per cent point on the cooling curve corresponds to the ultimate rise for the previous heating curve.

For example, if the rise at the instant of power shutoff has reached 135 degrees or 45 per cent of a 300-degrees ultimate rise, the cooling performance starts at the 45 per cent point on the cooling curve.

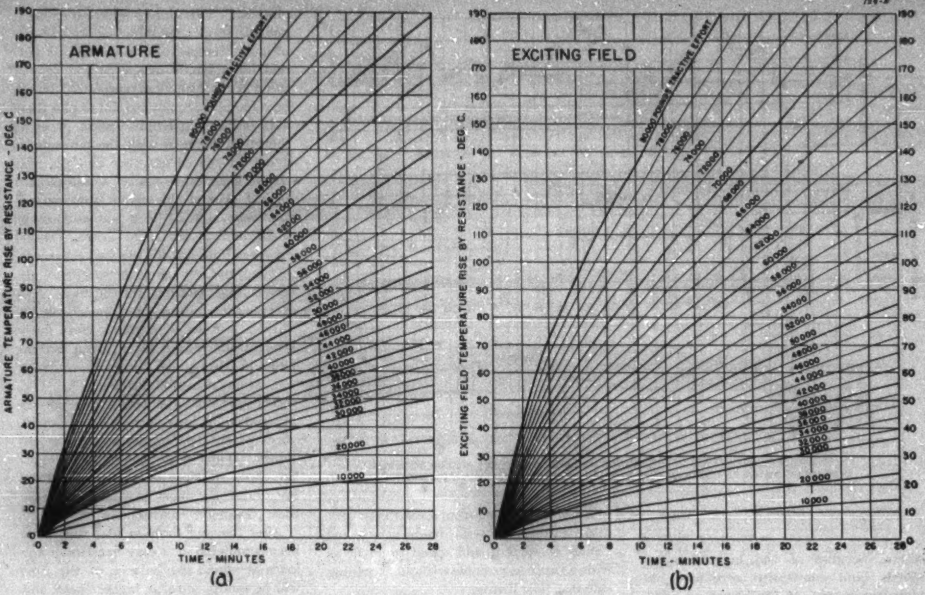
(*B*). Load reduced: In the case of a change to a new load with an ultimate rise lower than the temperature rise at the instant of load reduction, then the ultimate rise corresponding to the new load is considered as the zero per cent of the cooling curve and the ultimate rise of the previous load is considered as the 100 per cent of this new cooling curve. All rises calculated from the cooling curve must be added to the ultimate rise corresponding to the new load.

For example, it is assumed, as before, that the temperature rise has reached 135 degrees or 45 per cent of 300-degrees ultimate rise. Assuming now that the new load has a corresponding ultimate rise of 110 degrees, then the new cooling curve is determined as follows:

300-degrees rise is............100 per cent
110-degrees rise is............ 0 per cent
and the difference or 190-degrees rise is the full range or spread of the cooling curve.

The 135-degrees rise reached at the instant of load change corresponds to the percentage of 135 degrees minus 110 degrees (or 25 degrees) to 190 degrees which is 13 per cent on the cooling curve. Then this 13 per cent of 190 degrees and subsequent lower values of this percentage of 190 degrees are added to the new ultimate of 110-degrees rise to obtain the rise of the winding.

(5). *Time.* It is evident that the abscissae of the curves in figures 3*b* and 4*b* shown in minutes apply to actual times when starting from zero-temperature rise or cooling and that for all other conditions they apply to time increments. For example 45 per cent of 300-degrees ultimate rise on the cooling curve in figure 3*b* corresponds to 15 minutes. If power stays off for 10 minutes, the tem-



perature rise at the end of this period of cooling will correspond to that shown for 15 minutes plus 10 minutes or 25 minutes which reads 31 per cent. This, in turn is 93-degrees rise for the winding.

(6). *Effect of Increased or Reduced Ventilation.* The heating capacity of the traction motors is definitely affected by the amount of ventilating air. Figure 6 shows the relation between the temperature rise and the static pressure in the commutator chamber which in this case is 5.8 inches under normal rating conditions. The per cent shown in ordinates indicates the per cent increase or decrease of the ultimate temperature rise for any ventilating condition between four and seven inches of water static pressure corresponding to approximately 80 per cent to 110 per cent of normal air.

However, the heating curves are also affected by changes in ventilation in such a manner that the time to reach a given per cent of ultimate is shortened in about the same ratio as the ultimate rise is reduced (if the ventilation is increased). This has the effect of partly offsetting the gain obtained by reducing the ultimate rise in degrees. There is still an appreciable gain in temperature if the temperatures are from 80 per cent to 100 per cent of the ultimate. However, increased ventilation has very little effect on very short-time rises, say from 0 to 40 per cent of the ultimate, and this should be taken into account when higher ventilation is proposed to increase the locomotive short-time capacity.

Application to Temperature Study for a Complete Run

Figure 7 shows the performance of a 230-ton locomotive (of the type shown in figure 1), hauling a passenger train of 1,285 tons over a portion of the electrified territory.

Figure 5. Traction-motor temperature rise for slow-speed operation in weak field connection—5.8 inches static pressure

In addition to the usual profile, tractive effort, and speed charts, this figure includes a complete plot of armature and field temperature rises prepared by the use of the method which is the subject of this paper.

It will be noted that in this particular run the armature temperature rise is always higher than the field rise. This is characteristic of passenger train operation

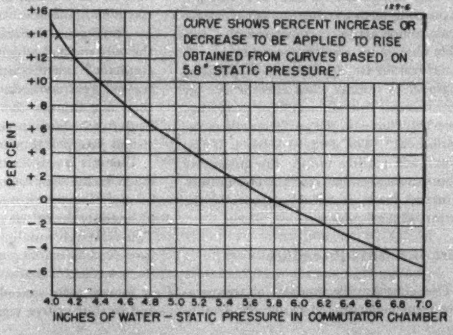


Figure 6. Effect of static pressure in commutator chamber of traction motors on rise by resistance

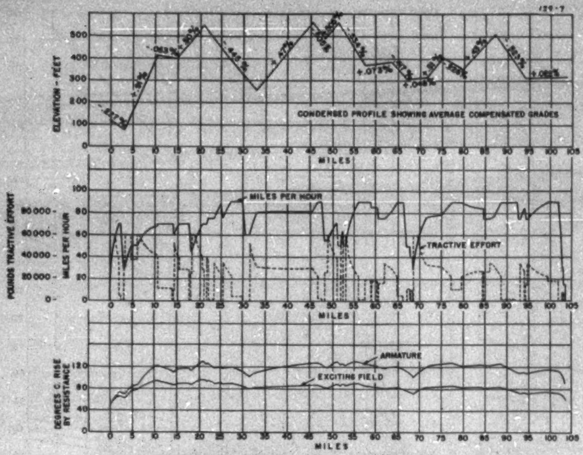

APPLICATION OF METHOD OF DETERMINING MOTOR TEMPERATURES IN CONNECTION WITH STUDY OF LOCOMOTIVE PERFORMANCE OVER PROFILE — 1515 TONS TOTAL WEIGHT LOCOMOTIVE & TRAIN

Figure 7

where, because of the high armature speeds (and consequent core loss) the temperature rise of the armature windings is higher than that of the field. The corresponding curves for a freight train run show field temperature rises in excess of those for the armature because of low armature speeds and relatively heavy currents.

This shifting of the seat of the limiting temperature rise from the armature to the field according to operating conditions is a further proof of the practical value of a method of analysis which leaves no gap in the coverage of temperature-rise data.

The actual process of applying the described method of temperature charting to a contemplated or actual train run quickly brings out the ease with which it is possible to determine the effect on the peak temperatures encountered of a possible change in operating conditions. It is natural for the application or operating engineer to wonder what effect a five per cent increase in train weight or in average speed will have on the performance of the equipment. The method subject of this paper will readily supply the answer to many such questions and thereby permit, in many cases, material increases in the output of the equipment.

Part II. Test Procedure

The considerable amount of temperature data incorporated in figures 3, 4, 5, and 6 was obtained from a relatively very small number of tests, made at selected values of current and speed to cover as wide a range as possible without exceeding safe test-floor limits.

(1). Ultimate Rises

The ultimate rises of the armature are shown on figure 8. Tests of four or five hours duration were held within the following limits:

(*a*). 1,900 rpm as a speed limitation.

(*b*). 130-degrees-centigrade rise from 1,900 rpm to 1,200 rpm.

(*c*). Below 1,200 rpm, the field heating limited the current to around 1,700 amperes.

Within this continuous capacity operating range which is shown by a dotted line, it was possible to actually determine the ultimate temperatures of the windings by measuring their resistance. This is the only method which gives accurate and consistent results since, by its use, a trained test crew can check within less than five degrees the results of any one load run.[3] Such accuracy permits consistent interpolation and extrapolation.

Ten to fifteen continuous runs were made within this range at the loads shown by circles on figure 8 maintained until the ultimate temperature rises were obtained. This relatively small number of temperature runs is made possible by confining the selection of loads, as shown, to three or four equally-spaced values of current and to four or five equally-spaced values of speed. This limited selection makes it possible to plot, as soon as obtained, the ultimate temperature rises against current for a family of speeds and against speed for a family of currents. It has been found especially helpful to plot these data on semilogarithmic curve paper as shown on figure 8 with the currents as uniformly-spaced abscissas and the rises on the logarithmic scale. When plotted against current the curves obtained are relatively straight-lined for a constant speed and a family of nearly parallel curves is obtained for the various speeds. In the same way using the speeds for abscissas and plotting the ultimate rises in ordinates on the logarithmic scale for various families of currents gives fairly straight-line curves for a given current and a nearly parallel family of curves for the various constant currents.

The fact that the test points line up along straight lines permits a very quick check of the test results as soon as obtained. Thus, if any results look doubtful, check runs can be made without delay under the most favorable and the most conclusive conditions.

After the first three or four runs have been completed, it is easy to estimate the loads at which the balance of the runs will be made, some at higher speed and lower current, others at lower speed and higher current.

In this way a rather complete picture of ultimate rises over the range of speed and current is very quickly obtained as shown in figure 8 and these parallel families of curves lend themselves to, and practically invite, very accurate interpolation. To a certain extent, these curves also make possible extrapolation in both directions, especially toward temperature rises in excess of the values which can be safely run on test. Beyond these limits of continuous load runs, further ultimate rise data are obtained by the use of short-time runs in conjunction with heating shape curves.

(2). Heating Curves

In connection with each ultimate rise or continuous load run, it is possible to obtain test points of the heating curve with very little additional testing effort by stopping the temperature load run 30 or 45 minutes after starting cold (i.e., zero initial rise). After the temperature rise of the motor winding has been determined at the moment of interruption of the load run, the run is resumed and carried to completion.

Dividing the rise obtained after 30 or 45 minutes by the ultimate rise gives the per cent of ultimate reached during the short-time run. This is plotted against

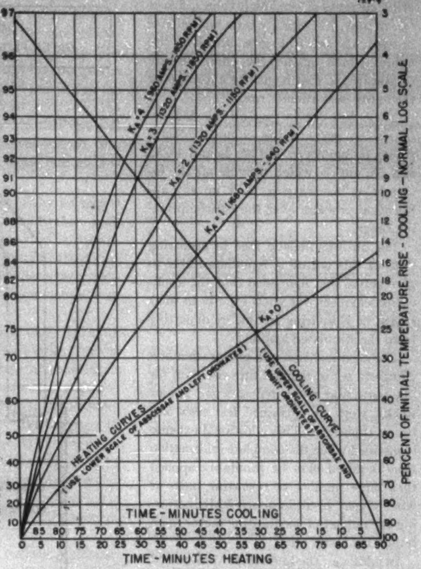

Figure 9 (right). Traction-motor armature heating-up and cooling curves at 5.8 inches static pressure in commutator chamber

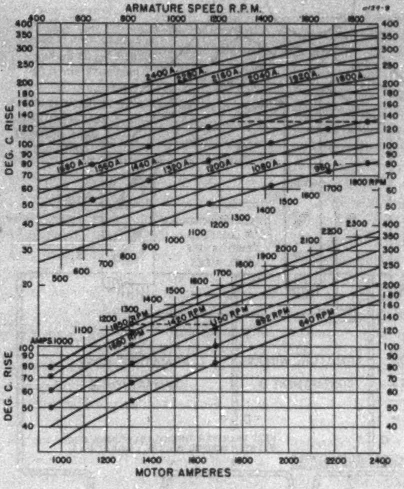

Figure 8. Traction-motor armature ultimate rises by resistance fo 5.8 inches of water static pressure in commutator chamber

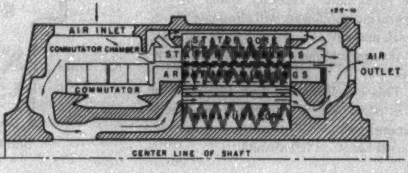

Figure 10. Motor ventilation and air passages

time on a semilogarithmic curve paper using an antilog scale as can be seen from figure 9. Several points are necessary to establish the general heating-up shape for a given load run. In addition to the 30-minute point obtained in conjunction with the continuous load run, other points at 10 or 15 minutes, 45 or 60 minutes are taken to establish the general shape.

Past experience and theoretical investigations have shown that these curves are of a logarithmic nature and, if one of the curves is accurately determined throughout its extent, other curves will be easily established from a small number of test points as follows and as shown on figure 9.

If the known curve (1,320 amperes 1,850 rpm) reaches 70 per cent of ultimate in 12.5 minutes and the test point on a new curve reaches 70 per cent of ultimate in 25 minutes, then we know that for any other per cents of ultimate, the time abscissa for the new curve will be 25/12.5 = 2 times the abscissa for the known curve for the same per cent of ultimate.

When enough of these shapes are drawn up and the time-abscissa ratios are established for various current-speed loads, then it is possible to find a definite relation between the time-abscissa ratio and the load conditions, which in turn permits the plotting of additional heating shapes at any other load. The curves shown for the armature on figure 3*b* and on figure 6 verify a time-abscissa ratio equal to 1+2.2 rpm/amperes or 1+47 miles per hour/amperes for this particular application. For convenience the index number K_A on the heating shapes was taken as 47 miles per hour/amperes and it will be noted that these index lines are numbered from 0 to 4.6.

The curves shown for the field on figure 4*b* verify a similar time-abscissa ratio this time expressed as 1+0.55 rpm/amperes or 1+11.6 miles per hour/amperes for this particular gear ratio and wheel diameter. For convenience the index number K_f was shown as one-fourth of 11.6 miles per hour/amperes so that the index number is 2.9 miles per hour/amperes giving a range of 0 to 0.26.

It is obvious that the ventilation of the motor as illustrated in figure 10 has a considerable effect on this spread of heating curves as affected by speed. If the ventilation of the field is considerably increased by design changes, this spread will be reduced because the field rise will be more nearly independent of the armature heating, in other words, less affected by speed.

(3). Complete Sets of Temperature-Rise Data

Thus as tests proceed, a complete set of data becomes rapidly accumulated, with a minimum amount of cutting and trying, since any test result, provided it is accurate, finds its place in the range which is being mapped out.

The ultimate rises plotted for values in excess of 140 degrees are obtained by a judicious use of the already determined heating curves in conjunction with short-time temperature runs at overloads which if maintained for a considerable period of time would produce temperature rises well above safe limits. Even at accelerating currents of very high values, five or ten-minute temperature tests and reliable heating curves will give ultimate rise values which extend the chart already established so that it may be applied over the entire performance range.

These test curves give all the data required to prepare the complete charts shown on figures 3*a* and 3*b*, 4*a* and 4*b*, 5*a* and 5*b*, and 6, which provide all the information necessary to work up any application problem over the entire operating range.

The authors believe that in preparing data of this nature it is indispensable to give actual test figures so that the application engineer will know exactly to what extent he is inviting trouble by departing from the stipulated loading.

The accumulation and preparation of a complete set of temperature-rise data for one particular motor requires two to four weeks' work by a trained test crew and by an engineer. This additional expense is justified when the complete information thus required may be profitably applied to a large number of operating units or when it may result in appreciably increasing the output of the limiting motor in an important installation.

In addition, the knowledge thus gained of performance capacity under diverse operating conditions will eliminate guesswork and will encourage definite planning in the application of motor-driven apparatus.

This concludes the first two parts of this paper which completely describe a general method of approach and investigation based on test results.

Part III. Empirical Analysis and Hydraulic Analogy

Empirical Equation of Ultimate Temperature Rise

It is now desirable to take advantage of the accumulated heating and cooling data to obtain an empirical formula expressing the temperature rise in terms of speed, current, and flux.

By extrapolating some of the data to zero current or to zero speed and by selecting other data at constant values of current and speed, it was found that the ultimate rise of the armature can be expressed for this particular motor as follows:

$$\text{Rise}=\frac{9\left(\frac{\text{rpm}}{1,000}\right)^{3/2}+18\left(\frac{\text{amperes}}{1,000}\right)^{3/2}+4.15\Phi^{2}\left(\frac{\ }{1,000}\right)^{1/2}\left(\frac{\text{rpm}}{1,000}\right)^{3/2}}{1-0.108\left(\frac{I}{1,000}\right)^{3/2}}.$$

Figure 11. Hydraulic analogy of armature temperature rise

This is an empirical relation which closely approximates the test results and may be considered as giving a fairly correct picture of the effect of speed, current, and flux.

The (3/2) power has been used because it expresses in one term a relation which normally would require several terms. The denominator represents the consequent effect on the temperature rise of the increase of the resistance of the copper with temperature.

Among many interesting applications this equation now makes it possible to analyze an important condition associated with heavy current overloads on acceleration. There is a critical value of current such that, above it, the I^2R loss is so predominant that the cumulative effect of increased I^2R losses with increased temperature brings the ultimate rise to infinity resulting in destruction of the winding at this load even in a very short time. This critical value obtains when the denominator is equal to zero which makes the ultimate rise infinity.

In the particular case which is being covered, this critical value of current is 4,400 amperes which can be compared to a normal continuous current of 1,560 amperes and a locomotive overload setting of 2,750 amperes. This critical value of current gives a rather definite idea of the safe range of overloads and is largely determined by the amount of copper in the winding.

Hydraulic Analogy

Many complicated physical relationships have been clarified by the use of a hydraulic analogy[3] which has proved particularly enlightening in explaining the temperature rise of electrical machinery and which has suggested the arrangement shown in figure 11.

A large tank with three compartments represents the entire armature. The water which is poured into these compartments represents the heat losses developed in the three main parts of the armature: commutator, winding, and core shown in figure 10.

These three compartments communicate with one another to indicate the possibility of heat flowing from one part to the other. Heat dissipation is represented by the flow of water through three discharge openings, one for each compartment and these openings are controlled in accordance with the rate of dissipation (armature speed and amount of ventilating air).

Compartment *A* represents the commutator. The commutator receives heat from brush friction and brush contact loss, both sources of heat being represented by two pipes supplying respectively losses which are a function of speed and losses which are a function of current. Some of this heat can be exchanged with the adjacent compartment through the path *ab* in either direction. Most of the commutator heat is taken away directly by the ventilating air and the surrounding air in which it rotates (see figure 10), and is shown as coming out of V_a.

Compartment *B* represents the armature winding, seat of the I^2R and eddy current loss. Since the I^2R loss is the predominant factor and since resistance increases with temperature rise, a float and valve *R* are shown which increase the amount of heat loss as the temperature rise goes up.

This compartment communicates with the two adjacent compartments *A* and *C* through the openings *ab* and *bc*. This opening *bc* serves to transfer a large amount of the armature copper heat through the slot insulation into the armature core shown in compartment *C*. The rest of the heat generated in the copper is taken away through surface ventilation on the end windings (see figure 10), as shown through V_b which opening, like V_a, is affected to a large extent by speed.

Compartment *C* represents the armature core. All of the core and part of the load loss are functions of speed and flux. These heat losses in addition to that which flows from the armature copper are discharged through the opening V_c which represents the ventilation through the longitudinal ducts in the core (see figure 10).

The temperature rise in each of these three parts of the armature can be compared to the rise in the level of the respective compartments where water is poured at a rate corresponding to the losses and where there is an opening at the bottom which is determined by the rate of dissipation. For the sake of simplicity, it is assumed that the flow through the orifice is proportional to the head and not to the square root of the head as is actually the case. A stable level or ultimate rise will be obtained when the level is such that water flows out at the same rate as it is poured in.

The rate of dissipation is by no means constant, but varies considerably with the operating conditions; in other words, the size of the openings should be regarded as determined by each operating condition, particularly if the amount of ventilating air is varied.

Let it be assumed now that the motor is operating normally with losses from all three sources. All three compartments are being filled at the same time and after two or three or four hours, stable levels will be reached in all containers. Of special interest, of course, is the rise of the armature winding which is measured by the level in the compartment *B* and which is the final limitation in the application of the motor and the loading of the locomotive.

The critical value of current previously referred to can be explained in the analogy by the additional cumulative action of the float mechanism *R* in increasing the flow of water in compartment *B* as the level rises. It will be easily realized that if the level rises high enough in *B* tank and if the water pours in fast enough (as in the case of extreme overload), no stable level is possible and the action of the float will cause a cumulative rise which will lead to faster and faster rises and finally to destruction.

An attempt will now be made to arrive at an equally general interpretation of the heating curves. Assumed first that S_S is closed (zero speed) and that S_I is wide open at the maximum opening (corresponding to the highest possible overload current on the locomotive motors), as the level rises rapidly, the float intervenes to open the valve still more and this somewhat delays the time at which stable temperature levels are obtained, since, so to speak, every time the temperature level approaches a stable point the float action tends to postpone the ultimate stabilization. However, since the value of current used is very far from the critical value of current, the level finally settles at what corresponds to the ultimate rise.

Under these "delayed" conditions (due to the increase in resistance as the temperature rises) the ultimate level or rise will be higher than the constant resistance and it will take a longer time to reach stability. It will also take a longer time to reach any given fraction or per cent of the ultimate rise than with constant resistance. For this reason, it can be said that the corresponding heating curve, expressed in per cent of the ultimate, is slower than would obtain with constant resistance and becomes the slowest of all heating curves within the operating range. This is the curve which is shown in the chart 3*b* by the index $K_A = 0$, and corresponds to maximum current and zero speed.

Assume that the motor remaining stationary, the valve S_S remaining closed, the valve S_I is partially closed to permit only a reduced flow. The level rises less rapidly at first but toward a lower ultimate which is reached more quickly (relatively speaking) because the float control modifies the spigot opening to a smaller extent. In this way there are obtained somewhat faster heating shapes shown in the figure 3*b* by indexes $K_A = 0.2$ or $K_A = 0.4$.

Let it be assumed now that, at a still lower value of current, the motor is brought up to speed. This amounts to closing valve S_I still further and to opening valve S_S. This also has the effect of opening V_a, V_b, and V_c wider because of the more favorable conditions for the dissipation of heat.

The initial rate of rise of the level in compartment *B* is faster because there are additional amounts of water pouring into *A* and *C* which have the effect of partly restricting the flow from *B* out of *ba* and *bc*.

This means that the rate now obtained corresponds to one of the faster heating-up curves shown in figure 3*b* by indexes $K_A = 0.6$ up to 4.6, the higher indexes and faster curves corresponding to the higher speeds, where a greater total amount of losses is dissipated more rapidly by a more complete utilization of the heat-dissipating ability of the motor.

COOLING CURVES

The cooling curves offer a quite different problem. In the heating-up process the rate of rise was determined by the opposition of two conflicting phenomena: (1) generation of losses, and (2) dissipation of losses, or, in other words, water pouring in and water coming out.

In considering the cooling conditions, there is only one of these phenomena, the dissipation of the losses, or, in the analogy used, the rate at which the tank will be emptied if S_I and S_S are simultaneously shut off.

Obviously this cooling or emptying

process is determined by only one set of conditions, the level in the three tanks or the temperature rises in the various parts of the motor and, if the difference between the levels in the three tanks is not excessive there shall obtain to all intents and purposes only one average cooling curve, which has been confirmed by tests. In fact, if there were a very pronounced difference in the three heads, it would tend to level itself out fairly rapidly giving a different rate of cooling for the first few minutes of cooling in the highest tank until levels have equalized.

Exciting Field Data

Figure 4*a* and *b* shows the set of charts prepared for the exciting field which give the same complete information as was given for the armature and which completes the coverage of temperature performance data. A hydraulic analogy similar to that for the armature could be used for the field (but with differently proportioned compartments and openings).

Summary and Conclusions

In the first part of this paper the authors have presented the complete set of charts necessary to work out for one particular motor the temperature rise for any service cycle. In the second part, they have shown in detail how to prepare these charts from a minimum amount of test data.

In the third part of this paper they have shown an empirical analysis of the relationship between temperature rise and the motor current and speed. Further, they have explained by a hydraulic analogy some of the combined phenomena on which this study is based.

Having completed these charts and analysis and having used them with satisfactory results for several years, the authors fully believe that similar charts can profitably be worked out for other types of motors and other complicated service applications and they hope that this paper will facilitate further practical interpretation of the already developed theoretical investigations on the heating and cooling of electrical machinery.

Inductive Co-ordination of REA Distribution Systems and Telephone Systems

K. J. PLUCKNETT
ASSOCIATE AIEE

W. T. SMITH
ASSOCIATE AIEE

T. A. TAYLOR
MEMBER AIEE

Synopsis: The Rural Electrification Administration and Bell System have been carrying on co-operative studies of the inductive co-ordination of REA distribution systems and rural telephone circuits since 1939. The results of these studies have indicated that the two systems can be satisfactorily co-ordinated when (*a*) the influence of the power system is controlled, (*b*) the separation in unavoidable exposures is adequate and reasonably uniform, and (*c*) the susceptiveness of the exposed telephone circuits is limited by care in design and maintenance. The more important factors controlling the influence of REA distribution systems and the susceptiveness of rural telephone circuits are reviewed and certain remedial measures applicable to the power system are discussed, with illustrations from the recent joint field work. Recent trends in the design of rural telephone circuits which result in improved susceptiveness are mentioned.

Introduction

THE inductive co-ordination of power and telephone distribution systems has been co-operatively studied for many years both by operating company engineers and by such groups as the joint subcommittee on development and research of the Edison Electric Institute and Bell Telephone System. The results of these studies have been published in the engi-

neering reports of the joint subcommittee and in a number of papers before the Institute. These studies were first largely concerned with co-ordination of urban and suburban distribution systems,[1] and only within the past few years has detailed consideration been given to the problems encountered in connection with distribution systems in rural areas. These latter problems were considered in a paper presented before the Institute in 1938,[2] which discussed the theoretical and practical aspects of the co-ordination of rural power and telephone systems and described certain remedial measures which were available at that time. That paper also explained many of the special terms employed in discussions of inductive co-ordination. The present paper makes no attempt to cover the fundamental factors but merely discusses their application to problems encountered recently in connection with the co-ordination of REA type distribution systems and rural telephone circuits, and describes the application of certain remedial measures which have become available since 1938.

Soon after the formation of the REA in 1935, representatives of that organization and of the Bell System discussed methods for handling the co-ordination problems associated with rural power line construction and it was agreed that these problems should be studied co-operatively and co-ordinative measures applied where necessary on the basis of the best over-all engineering solution. Accordingly, in July 1939 a group of engineers from these organizations met and agreed on a program to develop general methods to reduce as far as practicable the number of cases where detailed studies in specific exposures would be necessary. This was deemed important since the REA estimates that its distribution systems will ultimately total about a million miles of line throughout the United States. Arrangements were made to carry on co-operative field investigations in situations which offered an opportunity to obtain development information which would be useful in this connection as well as to assist in the solution of particular problems.

These studies have now been under way for more than a year and the results to date indicate that multigrounded rural distribution systems of the REA type and metallic telephone circuits can be co-ordinated satisfactorily, where the problem is handled co-operatively by the organizations involved. In order to accomplish this, consideration of the following factors is important:

(*a*). Unnecessary exposures between power and telephone systems should be avoided. Where it is necessary to create an exposure, the separation between the two systems should be maintained as nearly uniform as possible in order that transpositions in the telephone circuits will have maximum effectiveness.

(*b*). Perhaps the most important factor in limiting the inductive influence of the distribution system is the restriction of the mag-

*Telephone influence factor (TIF) is a measure of the harmonics present in a voltage or current wave, the individual frequencies being weighted in proportion to their inductive influence on exposed telephone circuits. The influence of a voltage is usually expressed as the product of rms kilovolts and TIF (abbreviated kv·*T*). Similarly the influence of a current is expressed as the product of rms amperes and TIF (abbreviated *I*·*T*). These terms are more fully discussed in reference 3.

Note: Numbers in parentheses represent 780-cycle contribution to total TIF or *I*·*T*.

nitudes of the harmonic components present in the voltage at the source of supply to the distribution system. This may involve limitation of harmonics originating in generators or in the power system from which the distribution system is supplied. The importance of harmonics present in the source of supply is often emphasized by the effects of resonance when the line is connected, as discussed later.

(*c*). A second important source of harmonics in the distribution system is the exciting currents arising in supply and distribution transformers. It is desirable to select transformers having relatively low harmonic exciting currents and to operate these transformers as nearly as possible at the rated voltages.

(*d*). Reductions in the inductive influence of three-phase portions of the power system may sometimes be obtained by balancing the lengths of single-phase extensions and the magnitudes of single-phase loads among the various phases. However, where triple harmonic transformer exciting currents are important contributors to the influence, little reduction will be effected by improving the balance.

(*e*). The susceptiveness of the telephone system may be minimized by employing transposed metallic circuits in the case of open-wire construction, and by the control of series unbalance and shunt unbalances (to ground) in both open-wire and cable circuits.

(*f*). So far as practicable in new construction and rehabilitation work or in converting from magneto to common battery operation, it will be desirable to take advantage of the improved susceptiveness of the newer types of subscriber station equipment.

(*g*). Unbalances in telephone central office circuits to which the rural telephone lines may be connected have been found to be of importance in several situations. Improvements in balance may be expected to result in lower noise levels.

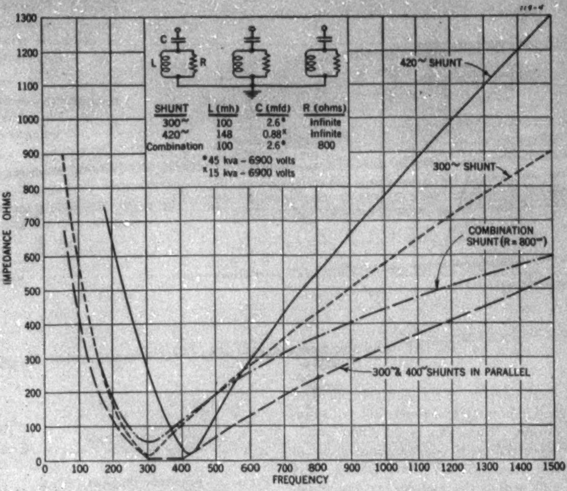

Figure 4. Phase-to-neutral impedances of various shunts for reducing 300- and 420-cycle components

In the usual case attention to the factors mentioned above in planning new construction will result in conditions which will make unnecessary the application of co-ordinative measures on a specific exposure basis. Some of the measures which have been used to bring about the general limitation of influence and susceptiveness on existing systems are:

(*a*). Improvement of the voltage wave shape of the particular generator or motor by means of resonant shunts or other devices at the machine terminals.

(*b*). Use of shunt capacitors, with or without associated reactors and resistors, on the distribution system side of the supply bank to improve wave shape or to minimize conditions of resonance.

(*c*). Use of wave trap in neutral of substation transformer bank to increase the impedance to residual currents at a particular harmonic frequency.

(*d*). Use of auxiliary device (such as autotransformer or regulator) to limit voltage on distribution system to values close to rated values for transformers employed.

(*e*). Rearrangement of distribution system to limit lengths of circuit supplied through a section of line involved in exposures with telephone plant. This may reduce the harmonic currents in the exposure.

(*f*). Improvement in balance of telephone circuits in central offices.

In other cases it has been found necessary to apply measures to telephone circuits in specific exposures, such as:

(*a*). Improvement in transposition arrangements of open-wire circuits.

(*b*). Improvement in series or shunt un-

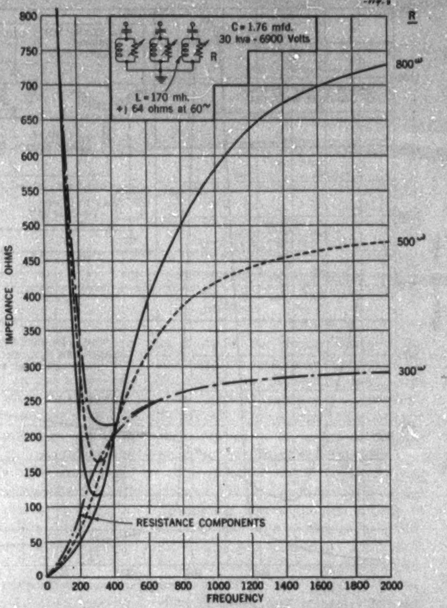
balance conditions of open-wire circuits, and associated equipment.

(*c*). Application of longitudinal impedance or drainage or a combination of these measures to particular circuits to minimize effects of series or shunt unbalances.

(*d*). Replacement of older types of subscriber equipment employing grounded lower impedance ringers for party line service by equipment having lower susceptiveness. This involves the use of higher impedance ringers at magneto stations. Several arrangements of varying degrees of effectiveness are available for common battery stations, including the use of auxiliary cold cathode tubes or relays in the ringer circuit, connection of an additional condenser in series with the ringer, or the use of higher impedance ringers with or without the double condenser.

Specific situations where certain of these measures were tested are described later in this paper. Due to the limitations of space, the results of tests of certain of the co-ordination measures in the telephone plant mentioned above, which were included in the various co-operative investigations, have not been presented in this paper, but are adequately described in the publications listed in the bibliography.

Figure 5. Phase-to-neutral impedance characteristics of various shunting arrangements having resistance component above 300 cycles



While most of the information in this paper is based on the co-operative studies by the REA and Bell System, the REA engineers have also made a number of studies co-operatively with other telephone organizations. Some of these studies have involved telephone circuits utilizing one wire with ground return. This type of circuit will have about 100 times as much noise as a metallic circuit for comparable exposure and influence conditions.[2] The results have shown that it is usually not practicable to limit the inductive influence of rural power systems to values which will permit the operation of ground return telephone circuits under noise conditions comparable with those existing before the power system was energized. However, in some cases it has been possible to reduce the inductive influence so that circuits having the shorter exposures could be retained on a ground return basis while the longer exposed circuits were converted to metallic operation.

The REA has also been carrying on work with the electrical manufacturers looking toward the limitation of harmonics arising in generators, transformers, and other types of power equipment. This work has already brought about worth-while improvements in generator wave shape.

Description of REA Distribution Systems

The three-phase four-wire multigrounded neutral distribution system operating at a phase-to-ground voltage ranging from 6,900 to 7,600 volts is generally employed in REA distribution systems. Extensions consisting of one- or two-phase conductors and multigrounded

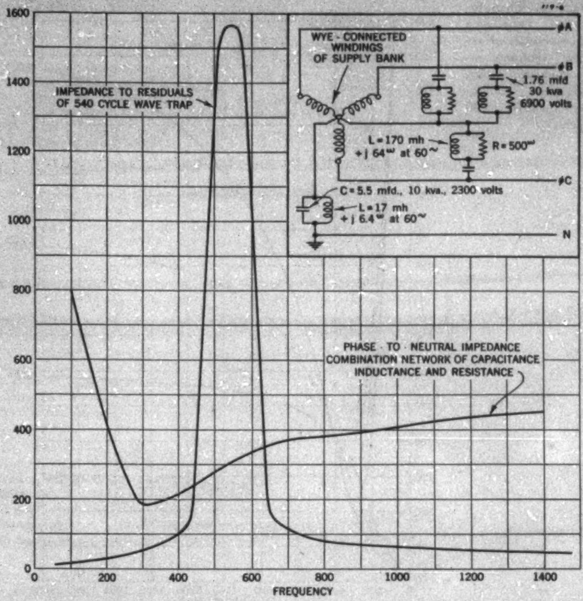

Figure 6. Characteristics and constants of combination network and 540-cycle wave trap

neutral, such extensions being metallically connected to the three-phase circuits, make up a substantial portion of each system. The systems are usually supplied from delta-Y transformer banks ranging from 75 to 2,000 kva (300 kva being the average size). The delta-connected windings on the supply side of the bank range in voltage from 2,300 to 110,000 volts. Power is usually purchased from existing systems, but is sometimes generated in Diesel or steam plants constructed and operated by the REA projects.

The largest proportion of the load on the REA systems is at present supplied single phase from transformers connected between phase wire and neutral and ranging in size from $1^1/_2$ to 5 kva. It is anticipated that the proportion of three-phase load will increase with the increasing use of power in rural areas. The size of the projects varies from small single-phase systems to extensive systems totaling over 1,000 miles and made up of substantial lengths of three-phase feeder with extensions. The average size project consists of approximately 350 miles of line of which about 90 miles is three-phase.

The connected kilovolt-amperes of distribution transformers varies greatly, depending on the type of area to be served. The average is around 5 kva per mile with peak densities up to 20 kva. It is anticipated that the connected kilovolt-amperes of transformers will increase with increasing load.

Description of Rural Telephone Plant

Until quite recently, most of the rural telephone circuits were operated on a magneto basis, but there is a definite trend in the Bell System toward the use of circuits employing common battery signaling, with local or common transmitter battery supply. These circuits are often connected to community dial offices (machine switching equipments of limited capacity). The conversion from magneto to dial operation is generally accompanied by improvements in outside plant conditions, replacement of open wire by cable, and frequently by the substitution of more efficient transmitters and receivers in an antisidetone circuit. These improved sets include higher impedance ringers for party line service. The common battery offices employ d-c signaling circuits which are grounded, in contrast with the magneto circuit, which is isolated from ground at the central office. This is the chief difference in the two types of office circuits from the inductive co-ordination standpoint, the central office ground often tending to increase the importance of series unbalances while at the same time reducing the effect of shunt unbalances.[2] Recent development work has indicated the practicability of improvements in the balance of the dial central office circuits, which are expected to minimize the necessity for special installations of longitudinal chokes or drainage circuits.

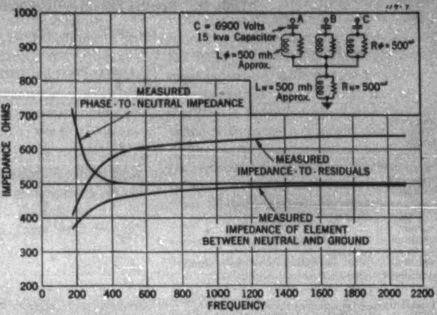
Generator Wave Shape

Control of the wave shape of generators purchased by the REA projects for installation in their own plants has been accomplished by including limits on the telephone influence factor (TIF)[3] of the generator voltage in the machine specifications. The open circuit TIF is a measure of the harmonics present in the voltage wave of a machine, the individual frequencies being weighted in proportion to their inductive influence on exposed telephone circuits. Most of these generators are rated below 500 kva and little attempt had been made in designing earlier machines of these sizes to limit the generator harmonics to values which would be considered satisfactory where the machine is to be connected to an extensive rural system of the REA type. As a result of co-operation between the REA and the manufacturers, the wave shape of these machines has been improved, without appreciable increase in cost to the REA projects on impairments in operating characteristics. Out of 32 generators installed and tested up to September 1, 1940, 26 machines had values of open circuit TIF of 25 or less, while the TIF of 15 of these was less than 10. These values compare favorably with those measured on the newer machines of larger size, which for some time have been designed to have relatively low values of TIF. No serious co-ordination problems attributed to harmonics in the impressed voltage have arisen in any situation where generators meeting the TIF limits have been installed.

Figure 7. Arrangement and impedances of experimental three-phase far-end termination



In a particular situation where no TIF limits had been imposed on the generator wave shape, the characteristics of the machine were such as to increase the inductive influence of the REA distribution system and to create a noise problem. In this case, a three-phase series resonant shunt applied to the generator bus was found to be a solution of the problem.

The generator was a 2,300-volt machine of 187-kva capacity supplying the distribution system through a bank of three 50-kva 2,300-volt delta to 7,200/12,450-volt wye-connected transformers. Measurements of the open-circuit phase-to-phase voltage wave shape of the machine indicated that approximately 400 volts of 13th harmonic (780-cycle) voltage was generated in the machine and the open-circuit TIF of the machine was 650. Each phase of the resonant shunt consisted of an air-core inductance of approximately 16 millihenries tuned to resonance at 780 cycles with a 5-kva 2,300-volt capacitor. The effective resistance of the shunts at the tuned frequency was approximately two ohms. Table I shows the effectiveness of the shunts in reducing the influence of the distribution system and the noise on a particular exposed telephone circuit.

The voltage TIF of the generator bus before the resonant shunts were con-

nected was substantially less than the open circuit TIF of the generator, indicating that the impedance of the system as viewed from the generator terminals is low compared with the internal impedance of the machine at 780 cycles. The impedance of the shunts was low compared with either the impedance of the generator or the system, and the 780-cycle component no longer controlled the bus voltage TIF with the shunts in service.

The effect of the shunts on the influence of the phase-to-ground and residual voltages of the 7,200/12,450-volt system and of the currents on the high-voltage side of the 150-kva bank is also shown in table I. The percentage reduction in the phase-to-ground voltage TIF and in the phase $I \cdot T$ products* due to the shunts is about the same as the reduction in TIF on the 2,300-volt generator bus. However, the reduction in the residual kv·T product* and $I \cdot T$ product was less, since frequencies other than 780 cycles, largely from transformer exciting currents, were important contributors to the residual influence.

It is of interest to compare the $I \cdot T$ products of the supply transformer with the corresponding values measured on the three feeders supplied from this bank. As indicated in table II, the arrangement of these feeders was such that there was a substantial unbalance between the currents in the various phases and, due to resonance effects, the harmonic residual currents on the feeders actually exceeded the corresponding current in the substation transformer. It is evident that the application of the resonant shunt substantially reduced the influence of each of the feeders, and in this case, it was not found necessary to consider improvement in the balance of the system.

Motors and Rectifiers

Resonant shunts of design similar to that used in the situation just mentioned present a comparatively simple method of improving the wave-shape characteristics of small motors as well as generators. Special care is necessary in the design of shunts for induction motors which may produce harmonics of varying frequency in order to obtain maximum effectiveness.

Rectifiers have not so far been an important source of harmonic distortion on REA distribution systems, but it is anticipated that this problem will arise as this type of system load increases. It is probable that cases of this sort can be handled by the application of selective devices similar to those employed in other situations.[4,5]

Transformer Exciting Currents

Another source of harmonic components on distribution circuits is the exciting current of distribution transformers. On REA systems, the ratio between the connected kilovolt-amperes of transformer capacity and the system load is relatively large. Consequently transformer exciting currents may control the inductive influence, particularly when the harmonics impressed on the system at the source or arising in loads are relatively small. The importance of transformer exciting currents has geen emphasized by recent changes in the design of certain transformers which have resulted in increases in the harmonic exciting currents. This is illustrated by the values in table III. Considering the three three-kva transformers, of which *B* and *C* are of the newer designs, there is a range of less than 2 to 1 in the rss* exciting current, while the exciting $I \cdot T$ products show a range of over 10 to 1, and the 540-cycle components show a range of 100 to 1. In the case of the five-kilovolt-ampere units, the more recent design (*E*) actually has a lower rss exciting current, but the exciting current harmonics and $I \cdot T$ product are larger. The 540-cycle component may be of particular importance in situations where there are exposures to three-phase portions of the power system, since this triple harmonic component appears as a residual on the three-phase circuits. As indicated later, in several cases it has been found necessary to consider means of reducing this component in order to make any material improvement in the over-all influence of the system.

---

*Explained in table 1.

It is well known that the harmonic exciting currents of distribution transformers increase rapidly with increases in the applied fundamental frequency voltages. This is particularly true of some of the more recent transformer designs, as indicated by the comparison of table IV.

In one situation, involving about 400 miles of line with about 1,300 kva of connected transformers, measurements of the lower frequency residual currents in the supply bank were made under two conditions of impressed voltage. As indicated in table V, an increase of five per cent in the voltage resulted in an increase of about 2 to 1 in the 540-cycle residual current. The 300-cycle component of residual current was largely produced by the 300-cycle component in the impressed voltage wave shape and was not appreciably affected by the increase in applied voltage.

In view of the field experience indicating the importance of this source in contributing to the over-all power system influence, consideration is being given by the REA to limits on the harmonic exciting currents of the transformers installed in the future since their experience indicates that the various designs have about the same characteristics from the standpoint of power system operation and cost.

Devices on Distribution-System Side of Supply Bank to Improve Wave Shape or Limit Effects of Resonance Between Line and Supply Transformer

Since REA distribution systems are usually supplied through transformer banks of relatively small kilovolt-ampere capacity, it is often practicable to improve the wave shape of the currents and voltages on the system by the use of shunt elements on the wye-connected side of the supply bank, utilizing the leakage reactance of the bank as a series element. The use of shunt capacitors for this purpose has been covered in a previous paper.[3] Capacitors are used, primarily in cases where the higher frequencies control the inductive influence, to lower the frequency of resonance between the reactances of the supply bank and of the distribution system. At the same time, the capacitor forms the shunt element of a low-pass filter to reduce the higher frequencies. Thus, in the absence of important lower frequencies in the influence, the over-all influence of the system is reduced. Data for one such situation are presented in table VI.

Resonant Shunts

Where the supply bank is relatively large, a considerable amount of capacitance would usually be required to provide adequate reductions in the impressed harmonics by the method described above. Also, there may be adverse resonance effects between the transformer reactance and the impedance of the capacitors at important lower frequencies where sufficient capacitance is used to provide the higher frequency reductions. In such cases, it may be more practicable to use a resonant shunt tuned to the particular frequency which is to be reduced. Such an arrangement can be made to have an effective resistance from 10 to 50 times lower than the reactance of the capacitors at the tuned frequency. The results obtained in a situation where a three-phase resonant shunt for 1,740 cycles was applied to the distribution system side of a 1,200-kva supply bank are indicated in table VII. Each phase of the wye-connected shunt consisted of a 15-kva 6,900-volt capacitor and an air-core reactor, with the impedance characteristics shown in figure 1. As indicated in table VII, the 1,740-cycle components of current and voltage were reduced in the order of 10 to 1 by the shunt, and substantial improvement was effected in the over-all influence and the noise on exposed telephone circuits. While the residual $I \cdot T$ product of the substation transformer was controlled by components other than 1,740 cycles, the results of measurements of the ground return $I \cdot T$ of one of the principal three-phase feeders showed that 1,740 cycles controlled before the application of the shunts.

Resonant shunts have a capacitive reactance at frequencies below the tuned frequency and an inductive reactance above that frequency. Care must be taken in applying such shunts to avoid adverse resonance effects with either the supply bank impedance or the impedance of the distribution system at any frequency of importance in the wave shape. In the case just mentioned, series resonance between the supply bank and shunt reactances occurred at 1,140 cycles, which

*Constants of devices shown in figure 6.

happened to be unimportant in the wave shape.

In one case, the reactance of the shunt was utilized as a capacitive element in parallel with the inductive reactance of the supply bank to offer a relatively high impedance to residual currents originating as transformer exciting currents or from unbalanced lengths of single-phase extensions connected to the various phase wires. In this case, the shunt constants were chosen to offer a low impedance at 660 cycles, a frequency prominent in the impressed voltage wave, and to resonate with the 300-kva supply bank reactance at 540 cycles, which was prominent in the load transformer exciting currents and important in the inductive influence of the system. Each of these shunts consisted of a 7.5-kva 6,900-volt capacitor and an air-core reactor of approximately 120 millihenries inductance, as shown in figure 2. The effectiveness of the arrangement is indicated in table VIII. The increases observed in the 420-cycle component with the shunts in service were due to the effect of a 420-cycle voltage in the impressed wave shape on the circuit consisting of the transformer inductive reactance and capacitive reactance of the shunt and line in parallel. However, the substantial reductions in the 540- and 660-cycle components were reflected in reductions in the over-all inductive influence and in the noise.

Combinations of Capacitors, Reactors, and Resistors

The arrangements so far considered are applicable where only the higher frequencies are important in the inductive influence, and where adverse resonance effects are not important. An arrangement which can be designed to offer an impedance which is substantially pure resistance over the voice frequency range has recently been developed by H. W. Wahlquist, and has been tried out on an experimental basis in several of the co-operative studies of the REA and Bell System. Figure 3 shows schematic diagrams of these arrangements as applied to three-phase or single-phase circuits. By properly proportioning the values of resistance, inductance, and capacitance, it is practicable to obtain a wide range of shunt impedance characteristics over the voice frequency range. Some of these are shown in connection with the discussion of specific cases.

Such an arrangement may be applied either at the supply point in the same manner as a shunt capacitor or resonant shunt, or as a resistance termination at the end of the distribution circuit. In the former case it may be used to reduce the effects of resonance between the substation transformer and system and, in addition, to limit the harmonic voltages impressed on the system from the source of supply. Where this is necessary, the shunt constants are chosen so that the impedance at a particular frequency is low compared with that of the supply bank. Where the arrangement is used to terminate a line in order to minimize the effects of line resonance, the constants are usually chosen to offer a resistance of the order of 200 to 500 ohms above about 300 cycles.

In two cases these combinations were applied to reduce the 300- and 420-cycle components present on the distribution system. In the first case (table IX) these components were relatively large in the voltage of the supply system and the 300-cycle component was increased 2 to 1 when the REA system was connected, due to resonance between the supply bank and system. It is of interest to note that the 300-cycle phase current was nearly as large as the 60-cycle current under this condition. Comparative tests were made of the effectiveness of (*a*) resonant shunts tuned for 300 and 420 cycles, (*b*) the 300-cycle shunt alone, and (*c*) a combination of capacitance, reactance, and resistance having the impedance characteristics shown in figure 4. As indicated in table IX, each of these arrangements effected substantial reductions in the influence of the system and in the resulting noise. The resistance arrangement has the advantage that it is not apt to introduce adverse resonance effects at higher frequencies which may be generated in loads connected to the REA system in the future.

The value of 800 ohms shunt resistance in this case was chosen so that the impedance of the combination at 300 cycles would be small relative to that of the supply bank. This was necessary since it was desirable to make considerable reduction in the 300-cycle voltage. In another case, where the 300- and 420-cycle components were not so prominent in the impressed voltage, and where the supply bank had a higher impedance, it was practicable to use lower values of resistance in parallel with the inductance, as shown in figure 5. Table X presents the more important results of these tests and indicates the comparative effectiveness of the various arrangements in reducing the resonance between the supply bank and system at 300 cycles. It is evident that the value of shunt resistance is not particularly critical. The 300-cycle resonant shunt was more effective than any of the various resistance combinations in reducing the 300-cycle component but less effective at 420 cycles. With either type of shunt in service, the 300-cycle line current was largely contributed by the exciting currents of the load transformers.

One phase of this system extended over 50 miles from the supply point. A 300-cycle voltage rise of about 2 to 1 was observed between the substation and the

distant point. With the resistance combination in service, the small magnitude of 300 cycles at the supply point makes this rise unimportant.

Combination of Shunts and Wave Trap in Transformer Neutral

Another situation somewhat similar to those described involved exposures of a telephone toll line to three-phase feeders supplied in two directions from a supply point. The influence of the feeders and the noise on the exposed circuits was controlled by 300, 420, and 540 cycles. The first two frequencies resulted largely from the effects of impressed voltage and were reduced by resistance shunts of the type already described. However, these shunts offered a low impedance to the 540-cycle residual currents, which originated in the exciting currents of the load transformers, and the over-all ground return $I{\cdot}T$ of one of the feeders was not appreciably reduced. In order to effect reductions in the 540-cycle component and to maintain the reductions at 300 and 420 cycles, a wave trap tuned for parallel resonance at 540 cycles was inserted in the neutral of the supply bank and the shunts were connected as shown in figure 6. The comparative results with these various arrangements in service are shown in table XI.

Resistance Termination at End of Distribution System

Where the inductive influence is largely the result of a condition of resonance, rather than abnormally large harmonics in the supply system voltage, it may be practicable to minimize the resonance effect by using a resistance termination at the far end of the three-phase circuit. This arrangement was tested in one case where resonance was encountered between the supply transformer and system at 660 cycles. The elements and impedances of the device employed are indicated in figure 7. This arrangement offered a resistance in the phase-to-neutral and residual circuits above 300 cycles, and was connected to the main three-phase feeder about 34 miles from the supply point. The results are shown in table XII and indicate about a 2 to 1 reduction in the 660-cycle voltages at the supply point and at the point where the device was applied. The phase current at the supply point was likewise reduced about 2 to 1 but the residual current was reduced over 4 to 1, due to the "balancing" action of the device on the three phases. The transformer exciting currents were not of controlling importance without the device. However, they became more important with the device in service because of the increase in fundamental frequency voltage resulting from the leading current taken by the capacitors.

The application of this type of termination appears limited to cases where resonance conditions are fairly acute. Where the system is extensive, it would probably be necessary to install terminations at the end of each main feeder.

There is always the possibility that an acute resonance condition of this sort may be set up at the time a system is initially energized, when the lines are lightly loaded. As the size of the system increases and the loads build up, the resonance point shifts to a lower frequency and the loads tend to damp out the resonance effects, although they may also contribute sources of harmonics. In several cases, acute noise conditions have occurred when the system was initially energized, and the growth of the system has tended to reduce the influence and noise. It is under such initial conditions that the termination appears most attractive as a remedial device.

Co-ordinative Measures in Telephone System

Co-ordinative measures which are available for improving the susceptiveness of exposed metallic telephone circuits were discussed in a previous paper,[2] and mentioned above. The joint work of the REA and Bell System has yielded no new co-ordinative measures but has emphasized the importance of continuing efforts to limit the susceptiveness of the outside plant and equipment associated with rural subscriber lines. Improvements in outside plant construction, such as extensions of cable on the more important rural routes, better transposition arrangements for open-wire exchange circuits, and the use of improved types of conductors employing rolled sleeve joints, are expected to result in lower susceptiveness of the rural plant. The development of a better balanced battery-supply relay with a fairly low longitudinal impedance has recently made available a new method of minimizing unbalances in dial central offices. This relay is to be employed in new offices in rural areas and will also be available for use in existing offices, as an alternative to the use of longitudinal chokes or drainage circuits,[2] in cases where unbalances are found to be important in contributing to the noise problem. The low longitudinal impedance of the balanced relays has the advantage that electrically induced voltages are drained from the circuit, and their effects on any shunt unbalances present in the line or station equipment are consequently minimized. The improvements in the susceptiveness of subscriber equipment mentioned earlier will also contribute toward better noise conditions in rural areas.

Conclusion

It is evident from the foregoing discussion that there is no universal solution to inductive co-ordination problems. However the experience already secured indicates that, in general, it is practicable to control the influence of the power system and the susceptiveness of the telephone plant so that adequate results can be secured at reasonable cost. The degree of effectiveness of the power system remedial measures has varied with the conditions of each individual case, the greater effectiveness being secured in cases where the influence was relatively high before the application of the devices. It is also apparent that in some cases several alternative arrangements of varying degrees of effectiveness may be applicable. In each case so far investigated at least one arrangement was found which reduced the influence to a point where satisfactory co-ordination with well-balanced telephone systems could be secured.

The success of the joint REA and Bell System inductive co-ordination work to date is a further clear indication that the best results not only from the standpoint of the organizations involved but also from the standpoint of the public can only be secured by close co-operation and joint study. The mutual understanding and background already created through these studies should form a firm basis for continued progress in this work.

Power Arc-Over on Overhead Distribution Lines and Newly Developed Equipment for Protection Against Conductor Burndown From That Cause

G. A. MATTHEWS
ASSOCIATE AIEE

Synopsis: With conventional types of switchgear and customary methods of circuit operation, power arc-overs resulting from transient faults on overhead primary lines cause unnecessary burndown of conductors and undesired operation of fuses. The majority of faults on overhead distribution circuits are of transient nature.

Factual data concerning arcing characteristics of covered and bare conductors were established by tests conducted under field conditions. They show that to prevent burndown of covered wire and to hold the arc damage within admissible limits, power arcs must be limited to one-half- to two-cycle (sixty-cycle basis) over-all time, depending upon size of conductor and arc current. Bare conductors are less liable to serious arc damage owing to the phenomenon of arc travel and to the self-extinguishing characteristics of arcs on such conductors. However, the duration of traveling arcs is sufficient to cause undesired operation of sectionalizing fuses unless the line is rapidly de-energized. Speeds of operation required to protect covered wire are also ample to assure against operation of fuses on transient faults.

New switching devices capable of meeting the required one-half- to two-cycle initial circuit clearance have been developed as part of this project. They also provide for automatic reclosure and a sequence of time-delay openings and reclosures before lock-out. Simplicity of construction, ease of installation, and self-actuating principles which dispense with auxiliary power requirements, make investment sufficiently low to bring these devices within the realm of practicability for low revenue distribution circuits as well as the more important distribution circuits. They are adaptable to existing and new circuits alike.

General

FAILURE of overhead primary distribution lines has long been a problem of electric utility operators, despite the fact that the lines possess adequate mechanical and electrical strength to withstand normal interferences. Many of these failures are the result of conductor burndown caused by power arc-over. Table I lists all cases of trouble during 1938 and 1939 on the Detroit Edison distribution system in which primary wires were down. Of the totals shown, investigation indicates that at least 60 to 70 per cent of these cases were initially of the transient fault class in which the wires would not have burned down if the arc had been interrupted soon enough.

It is evident that burndowns resulting from power arc-overs have their effect on service continuity, although in the opinion of many utility engineers the service now rendered to the various classes of customers is sufficiently satisfactory and in keeping with the character of the loads served. However, the public and maintenance employee hazard as well as costs associated with wires down is, or should be, a matter of serious concern to all operators, and it is this phase of the situation that was chiefly responsible for the studies and developments dealt with in this paper.

From the standpoint of service continuity, the problem of power arc-over becomes more serious as our systems expand and our distribution circuits reach further and further into the outlying and rural districts with proportionate increases in exposure of the lines. Accompanying this, we have the increased difficulty of patrol due to the greater distances and often the lack of good or even passable roads. The customary use of bare wire for rural extensions further complicates the problem because the performance of bare conductors under short-circuit conditions is different from that of covered conductors.

Weatherproof covering, when aged or wet, becomes less effective in preventing short circuits when conductors swing together or are bridged by conducting objects. When breakdown of the covering occurs, the resulting short circuit is of the arcing type because the covering serves as a mechanical spacer preventing metal-to-metal contact. Faults between bare conductors may be of the arcing type or they may be of the metal-to-metal type which cannot be burned clear.

The use of ring primary construction has been found to be an effective means of reducing service outage caused by overhead primary failures, but these measures do not remove or reduce the possibilities of wires down with the accompanying hazards. Furthermore, this scheme is applicable only in the high load density areas where short distances and concentration of customers make the arrangement physically and economically possible. Automatic breakers, sectionalizing fuses, and various types of protective devices have found their places in distribution circuits, although we still experience cases of trouble in which lines are burned down unnecessarily and sectionalizing fuses are needlessly blown.

Let us look at the distribution circuit as a whole and review the usual method of operation. We find the distribution transformers connected to the line through primary fuses to protect the main circuit from troubles that may develop in the transformer or its secondary circuit. We may find sectionalizing fuses protecting the feeders from troubles on the branches. These devices require energy for their operation—energy in the form of a flow of current in excess of that which the fuses are designed to carry under normal conditions. Obviously, if they are to function when a fault occurs, the flow of fault current must be con-

tinued for a long enough time to supply the amount of energy required for that operation. Again, if a fault on the line is not cleared through fuses, continued flow of fault energy is desired to burn the fault clear, if possible. If, in this attempt, the line burns down at the point of fault, the resulting hazard there, although undesirable, is thought to be less serious than hazards that might accompany the total shutdown of the circuit for a prolonged period.

To provide the necessary energy to accomplish these things, the opening of the station breaker is delayed for an appropriate period after fault inception. Moreover, if the fault has not cleared when the breaker recloses, the delayed opening cycle is repeated one or more times in a further effort to clear the trouble before the breaker locks out. On circuits not equipped with breakers it is the general practice to use fuses in an attempt to clear the faulted section without wire burndown.

With this system of operation, a faulted transformer or a fused section of the line which has become short-circuited will be promptly cut off from the rest of the circuit; or a fault on an unfused section may be promptly burned clear so that service, even though it may reach only part of the customers, can be restored at once. But what of the case where lightning paves the way for power arc-over on the line? The power arc may continue as long as energy flows into the line or until fuses are blown or the line is burned down. Here the condition that causes the short circuit or initiates the fault is present for only an instant; yet, intentional delay in interrupting the circuit deliberately provides energy to support the power arc with all its destructive forces. The same sort of thing happens when wires momentarily swing together, and, in fact, when any type of transient fault occurs, if we define such faults as those in which the initiating cause is of momentary nature—lightning, wires swinging together, small conducting objects such as baling wire and radio antenna wire across the line, are all examples of this type. It is apparent then that the delayed initial opening works to advantage on faults of the persistent type but may cause needless damage when faults of the transient type are encountered.

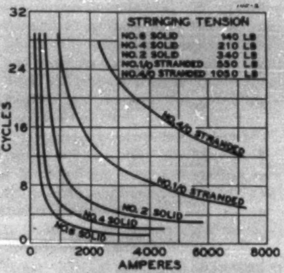

Figure 2. Burndown characteristics of covered copper wire at 5,000 volts; conductor spacing 28 inches

These considerations suggest the desirability of using equipment of a type such that arcs resulting from transient causes will not persist long enough to cause line burndown or fuse operation, but in the cases of persistent faults the fuses will blow or the wires burn down to clear the circuit. We cannot expect the station breaker to differentiate between types of faults on its initial operation, for it has no way of knowing the nature of the trouble with which it is dealing, but we could initially assume every fault to be transient and treat it accordingly. In those cases where the assumption is incorrect and the fault proves to be persistent, we could subsequently treat it as such. Thus, unnecessary burndown and arc damage, and undesired fuse operations, could most likely be avoided when faults are initiated by transient causes. The ratio between transient and persistent faults on overhead distribution systems is difficult to determine accurately from operating records because adequate evidence is usually lacking. Estimates, made from time to time by various individuals and for various types of systems, indicate figures ranging from about 50 to 90 per cent as the relation of transient faults to the total number of faults. It is the author's opinion that of all the faults occurring on the Detroit Edison distribution system about 60 to 70 per cent are initially of transient nature. The Detroit Edison distribution system is operated at 4,800 volts ungrounded and often combines in the same circuit both covered and bare wire.

It will be recognized that the scheme of breaker operation in which "instantaneous" tripping is used for initial breaker opening, succeeded by reclosure and a series of time-delay operations, follows the same patttern as the operating sequence suggested in the previous paragraph. The so-called instantaneous tripping, however, does not accomplish instantaneous circuit interruption because the relays require a certain amount of time for their operation and a relatively much longer time is required for the breaker contacts to part and the arcing at the contacts to cease. Although instantaneous tripping of conventional breakers is successful in many cases in preventing fuse operation on transient faults, the breakers are in general too slow to save covered wire from burndown. It is natural then to inquire as to the necessary speed of interruption if burndown or serious arc damage is to be avoided in case of transient faults, and as to how these requirements vary with different sizes of wire, different spacing and configuration of conductors, and with different values of current in the arc.

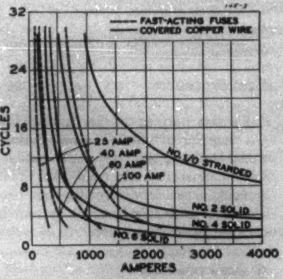

Figure 3. Comparison of the characteristics of fast-acting fuses with burndown characteristics of covered copper wire

Since no data were available with which these questions could be answered, a test project was undertaken to produce factual information upon which an intelligent at-

Test Procedure

For this purpose an experimental line of characteristic design using conventional hardware was set up in an outdoor laboratory so that test conditions would simulate actual service conditions. Provision was made for drawing the tension in each size of conductor tested to the value used in regular construction practice. Both bare and covered conductors of the sizes in common use in the company were tested in turn. The covered wire was copper with the standard triple braid weatherproof covering and the bare wire included the ACSR type, bare copper, and Copperweld wire. The covered wire was tested at a horizontal spacing of 28 inches which is the closest horizontal spacing used in the company's distribution system. The bare wire was tested at horizontal spacing of 58 and 88 inches, and at vertical spacings of 12, 18, 24, 30, and 43 inches.

All tests were made single phase, ungrounded, at 5,000 volts, 60 cycles. The fault current was controlled by series reactors and was varied between 80 and 7,000 amperes. The test circuit was arranged so that the flow of fault current could either be sustained until the arc cleared itself or the line burned down, or it could be limited in time duration to $^1/_2$ cycle on a 60-cycle basis ($^1/_{120}$ second).

The electrical performance of the test circuit was recorded with a magnetic oscillograph energized by instrument transformers connected as shown in figure 1. By this scheme of connections the exact instant of the parting of the conductors could be determined.

Short circuits between conductors were initiated in various ways. To simulate

power arc-over resulting from small conducting objects across the line, a single strand of No. 40 copper magnet wire was drawn across the conductors. The magnet wire was found to fuse in an average of about $^1/_{40}$ cycle, thus establishing the arc-over. To simulate arcing resulting from conductors swinging together, the conductors at mid-span were held in close proximity to one another by tying them with the fine magnet wire. When the line was energized, the fine wire fused allowing the conductors to swing apart. Since no practical difference could be found in the effects of arcs initiated by these two methods, the data from the two types of tests were averaged.

In other tests tree limbs of various sizes and of different kinds of wood, both green and dry, were laid across the conductors to simulate the condition where tree branches fall or are blown into the line.

In initiating the arcs on bare conductors it was only necessary to place the short-circuiting medium in contact with the wire. In the case of covered conductors the covering was in some instances removed all around over a length of two inches to expose the conductor; in other cases contact with the conductors was established by common pins forced through the covering. There was no distinguishable difference in the results of these two methods, and again the data were averaged as a whole.

Results of Tests on Bare Conductors

The motorizing action of the current flux of an arc between line conductors always tends to propel the arc along the line in the direction away from the power source. Under this force, an arc between smooth bare conductors will travel freely along the line. As it moves, the length of the arc "loop," or the ionized stream which carries the arc current, becomes greater and greater until finally it is broken and the arc is extinguished. If, however, the arc in its travel encounters an object, such as a splice in the wire, insulator tie wires, or any similar object that will serve as a point electrode, the arc will become anchored at that point and usually will continue until the conductors burn down or the fault current is interrupted in some other manner. Likewise, tree limbs and similar faults that cause arc-over will prevent the arc between bare conductors from traveling normally. In such cases the arc may periodically leave the location of fault and travel far enough to extinguish itself; but it will generally restrike at the original location and continue this performance until the line burns down or the limb, if it is sufficiently small, burns clear of the line.

The wind also has a marked effect upon the performance of traveling arcs. During certain tests, when the wind happened to be blowing in the same general direction as that of the force propelling the arc, it was observed that speed and extent of travel were increased. When the wind blew in the opposite direction, arc travel was retarded and in some cases the direction of travel was even reversed; that is, the arc was forced to travel toward the power source.

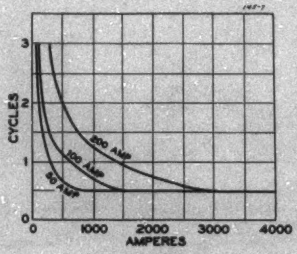

Figure 7. Switching speed of shorting contactor

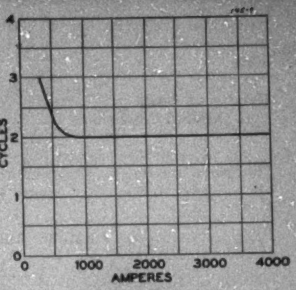

Figure 9. Switching speed of fast-opening and reclosing breaker

These outside influences served to accentuate the normally erratic performance associated with electric discharge so that it was necessary to repeat each test, particularly those of major interest, several times to obtain dependable averages.

Table II gives the results of the tests on bare conductors in which the arcs were initiated with the fine magnet wire and in which the conductors were spaced horizontally at the distances indicated. Table III gives the results of similar tests with the conductors spaced vertically. In all these cases the arcs had a clean sweep along the line and voltage was maintained until the arc blew out. Under "Duration of Arcing" in these tables, the figure shown as maximum in each case is that for the test in which the arcing continued the longest, the minimum figure is that for the test in which the arcing was the shortest, and the average figure represents the average for all tests under the indicated conditions. The extent of travel is given as an average and general

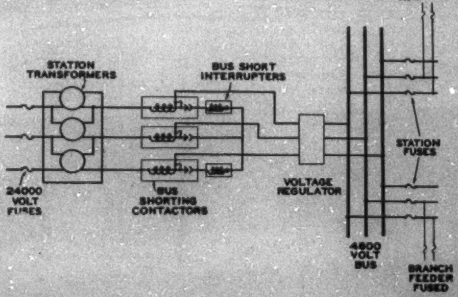

Figure 8. Application of bus-shorting contactors with interrupters to suburban stations with fused feeder circuits

comments concerning the amount of conductor burning are given under "Remarks."

Results of Tests on Covered Conductors

Arcs on covered conductors are prevented from traveling by the presence of the covering. If the arc is allowed to continue, it concentrates its heat at the points where the covering is punctured or the wires are exposed with the result that the line is quickly burned down.

In the first series of tests on covered wire, voltage was maintained on the line until after conductors burned down so that critical values of arc current and duration of arcing could be determined. Arcs were initiated by the fine magnet wire and the instant of failure was determined from the oscillograms as previously described. The results of these tests are shown graphically in figure 2. The curves represent the locus of combinations of arc current and duration of arcing which are just sufficient to cause fusion of the different wires. Thus, any combination of current and time represented by a point on the curve, or to the right of the curve, will cause burndown of that particular size of wire; combinations represented by points to the left of the curve will not cause actual failure of the conductors but will result in varying degrees of damage, depending upon the proximity of the points to the critical curve.

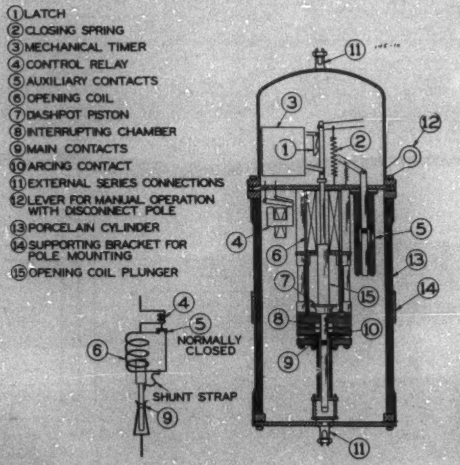

Figure 10. Cross-sectional view of fast-opening and reclosing breaker

The average distribution system has a wide range of fault currents for the different fault and circuit conditions, the maximum possible values obviously being dependent upon the impedance of the circuit up to the point of fault. Since these values are fixed by the characteristics of the circuit and the power available at the source, it is evident that the only function subject to control is the duration of arcing. If the duration could be made sufficiently small, it can be seen from figure 2 that, even though the fault current were high, the conductors could be saved from burndown. This, however, is not enough for practical purposes, for the damage would have to be limited to such a degree that the reduction in cross section of the wire at the point of arc burn would not seriously reduce the physical strength of the wire.

To explore the possibilities of limiting arc damage to admissible amounts, a second series of tests was run in which arcs of various current magnitudes were limited in duration to one-half cycle. The arc-damaged wires were then tested in tension and the reduction of strength determined from comparison with the tensile strength of undamaged wire. The results of these tests are shown in table IV.

Results of Tests With Tree Limbs Across the Line

The following general observations were made during these tests:

1. Tree limbs across the line may cause burndown of any kind of conductor.
2. Limbs of soft or pithy wood are more likely to burn clear of the line than those of hardwood.
3. Limbs of any kind of wood, if over one-half inch in diameter, will generally cause line failure if power arc-over is established.

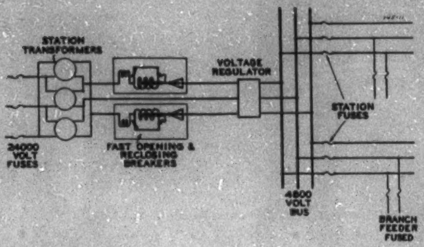

Figure 11. Application of fast-opening and reclosing breakers to light-capacity feeder circuits

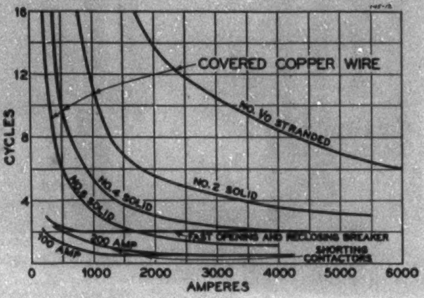

Figure 12. Burndown characteristics of covered copper wire compared with switching speeds of new devices

Analysis of Results

Referring to the results of tests on bare conductors (table II) and taking the data for tests at 58-inch horizontal spacing as a whole, it is seen that, although the arcs were self-extinguishing and did not cause burndown of the line, they persisted up to a maximum of 78 cycles.

Because of the susceptibility of bare conductors to metal-to-metal faults which cannot be burned clear by arcing, sectionalizing fuses are often used in circuits containing bare wire. It is evident from the tests that, with time-delay initial opening, practically any transient fault on the bare sections of such lines will cause the blowing of sectionalizing fuses, although the line itself may remain in perfectly good condition. It might be pointed out that less arc damage to conductors than that reported in the results would be expected in actual service since the duration of arcing would be held to the blowing time of the fuses. Nevertheless, for transient faults the unnecessary operation of fuses causes interruption to a portion of the circuit and long outage may result. The use of repeating type fuses to overcome this difficulty naturally suggests itself, but it must be remembered that the effectiveness of these devices entails frequent inspection and patrolling of the line.

Comparison of the results of tests at 58- and 88-inch horizontal spacing (table II) shows the influence of the wider spacing in reducing the duration of arcing. It can be seen from table III that for the similar wire spacings arcs persist longer on the vertical than on the horizontal configuration—damage to the conductors is correspondingly greater.

The results of the tests on covered wire (figure 2) serve to explain the inadequacy of conventional protective devices to save such wires from burndown or serious arc damage under arcing fault conditions. This is particularly true of the smaller sizes of wire which constitute, by far, the largest percentage of conductor mileage of the whole distribution system. The inability of representative fast-acting fuses to protect covered wire is shown in figure 3, where burndown characteristics of the wire and the blowing characteristics of the fuses are compared directly.

On the basis of the figures of table IV it was possible to reach conclusions with respect to the limiting duration of arcing on various sizes of covered wire if the conductors are to remain in suitable condition for continued use. These values for the range of fault current usually associated with the different sizes of conductors are given in table V.

Having thus established the speed of interruption necessary to avoid needless burndown and serious damage to covered conductors in case of transient faults, it was apparent that speeds adequate for the wire would also protect sectionalizing fuses from operation on transient faults and, therefore, the use of the fuses would be enhanced.

It must be remembered, however, that in addition to transient faults there still remains the persistent type for which energy must be supplied for the intended operation of fuses, or where there are no fuses, to burn the fault clear to avoid total outage of the circuit. The conventional reclosing breaker with time-delay relaying is entirely satisfactory for that operation but, due to the inertia of its parts and its own inherent arcing time, which is about two cycles giving an over-all time of six to eight cycles, it does not lend itself to speeds of operation anything like the required one-half- to two-cycle over-all time, which must be obtained if our objective is to be realized. A survey of commercially available equipment failed to disclose any devices suitable for the purpose and no new commercial developments were in sight. The Detroit Edison Company, therefore, developed three types of equipment which are described in the following sections of the paper.

Fast-Switching Equipment for Circuits Having Reclosing Station Breakers

The device developed for use in combination with station breakers is called the shorting contactor. Its function in case of fault is to metallically short-circuit the line, phase-to-phase, on the source side of the section of the line to be protected. This action collapses the line voltage with such speed that any arc accompanying the fault will be extinguished before objectionable damage occurs to the conductors and before operation or damage to any fuse can take place. After this operation the relatively slow-acting station breaker functions to open the circuit in the usual manner and it is intended that this initial opening will be accomplished by "instantaneous" tripping. The opening of the breaker clears the metallic short circuit applied by the shorting contactor, whereupon contacts of the shorting contactor separate under no-voltage conditions and the device locks in the open position for a predetermined time. If the fault is of transient nature, the entire circuit is left intact so that when the station breaker recloses, service is restored to the whole line. It is also intended that the breakers be arranged for "immediate" first closing which, with conventional breakers, can usually be accomplished in about 30 cycles. This time added to ten cycles, which is approximately the fastest speed at which conventional breakers can be made to open the circuit with "instan-

(c)—No. 2 wire one-half cycle protected by shorting contactor

(*d*)—No. 2 wire two-cycle pro tected by fast-opening breaker

Figure 13. 1,500-ampere arc burns on copper wire protected by the newly developed devices

taneous" relaying, gives a total interruption of about 40 cycles.

If we assume now that the fault instead of being transient is in reality persistent, no harm has been done in the initial attempt to clear the trouble, and little time has been lost. We are then at liberty to apply the usual reclosing cycles with time-delay relaying, the breaker being free of further operations of the shorting contactor during this interval since the latter has automatically locked out. After a sufficient time is allowed for the breaker to have completed its reclosing cycles, the shorting contactor automatically resets and is ready for the next fault.

A diagrammatic view of the shorting contactor is shown in figure 4. It is series operated, self-contained, and fully automatic, requiring no auxiliary circuits or power supply. It is designed for pole or station mounting and can be either air or oil insulated. Being series operated, it is connected in one side of the circuit by means of terminals (1). A lead from the opposite side of the circuit is connected to bottom terminal (8). Figure 5 shows a typical application to a three-phase, ungrounded circuit. It will be noted that the shorting contactors are located a short distance out on the line from the station. If they were located directly at the station, the short circuit caused by the fault would be transformed into the equivalent of a metallic bus short which, on stations of comparatively large size, would cause undesirably heavy shock to the station equipment. The effectiveness of the impedance of the line near the station in cushioning the shock is shown in figure 6 where the steepness of impedance gradient near the station is set forth for typical circuits having different values of bus short-circuit currents.

Table IV. Decrease in Tensile Strength of Insulated Wire Due to Arc-Current Damage

Arc-Current (Amperes)	Duration of Arc (Cycles)	Breaking Load of Arc-Burned Copper (Pounds)	Reduction of Strength	
			Pounds	Per Cent
No. 6 covered copper wire—initial breaking load, 1,165 pounds(average of six specimens)				
400		1,020	145	12.4
700	1	990	175	15.0
1,000	3/4	970	195	16.8
1,100	3/4	940	225	19.3
1,500	5/8	830	335	28.8
1,900	1/2	795	370	31.8
No. 4 covered copper wire—initial breaking load, 1,680 pounds (average of three specimens)				
2,500	3/4	1,265	415	24.7
4,300	5/8	1,225	455	27.0
No. 2 covered copper wire—initial breaking load, 2,820 pounds (average of three specimens)				
4,300	5/8	2,315	505	17.9
7,000	1/2	2,225	595	21.0

In general, No. 6 wire, when built into lines, is applied so that the tensile stress will not exceed 560 pounds. For No. 4 and No. 2 wires these figures are 920 and 1,200 pounds, respectively, under the most severe loadings anticipated.

The shorting contactor is designed to operate at current values 50 per cent over the normal load-current rating of the series coil. Rated load currents can be carried continuously without exceeding normal temperature rise limits, and loads up to 150 per cent of rated load have been carried for several hours without damage to the equipment.

The curves of figure 7 show the switching speed of the shorting contactor with coils of three different load-current ratings. It will be noted that all curves become flat at one-half-cycle over-all time. The different coils are interchangeable in the same housing.

It might be mentioned that the principle of de-energizing a circuit by applying an artificial short circuit at the source for the purpose of extinguishing line arcs is not new. It was suggested many years ago but, as originally proposed, there were no means by which operation within one-half cycle could be accomplished and no provision was made for holding the short-circuiting element inoperative after the initial operation. In the shorting contactor the control mechanism functions to lock the contacts in the open position within four cycles after the plunger resets and, as now built, the lockout period can be adjusted for any length of time up to four minutes.

Application of Shorting Contactor to Circuits Fused at the Station

For the lower capacity circuits that do not warrant station breakers, another form of the shorting contactor has been developed. In this form the contactor has its own interrupter to break the artificial short circuit which it applies between phases. Figure 8 shows an installation of this equipment from which it can be seen that the interrupter is connected in the short-circuit lead from the contactor and that it carries no load current. The design principle of the interrupter was developed by The Detroit Edison Company a number of years ago. In normal operation in this application the interrupter is in the closed position. When a fault occurs, the contactor short-circuits the line through the interrupter, thus collapsing the voltage. Current through the interrupter causes it to open and lock out for a predetermined time. This removes the metallic short circuit and allows recovery of line voltage. If the fault is transient, service is restored but, if the fault persists, the shorting contactor is prevented from de-energizing the line again, since the interrupter is locked in the open position. Fuses are then brought into play and serve to clear the fault. Although the interrupter is capable of opening the artificial short circuit within one cycle, it is purposely delayed in this operation for six cycles to avoid the possibility of re-establishing an arc at the initial location of fault. After a prescribed time, the interrupter automatically resets.

Table V. Approximate Limits of Duration of Arcing on Covered Copper Wire if Serious Loss of Mechanical Strength Is to Be Avoided

Size of Conductors	Current Range (Amperes)	Limiting Duration of Arcing (Cycles)
No. 6	Up to 500	3 to 2
	500 to 1,000	2 to 1
	1,000 to 1,500	1 to 1/2
No. 4	Up to 1,000	3 to 2
	1,000 to 2,000	2 to 1
	2,000 to 4,000	1 to 1/2
No. 2	Up to 2,000	3 to 2
	2,000 to 5,000	2 to 1
	5,000 to 7,000	1 to 1/2
No. 1/0*	5,000 to 10,000	2 to 1/2
No. 4/0*	8,000 to 15,000	2 to 1/2

*Values shown for these sizes are estimated.

This type of installation is particularly suited to stations where a large number of small conductors radiate from the station bus as indicated in figure 8. Such stations are usually of sufficiently small capacity so that application of the short circuit directly at the station is acceptable. Since the total interruption for each operation is only six cycles, there is no particular disadvantage in de-energizing the bus to protect one line from damage; a six-cycle interruption is hardly perceptible to the customer.

Two trial installations of this type, protecting two circuits each, have been in service on the Detroit Edison system for over a year and have given a good account of themselves.

Fast-Opening and Reclosing Breaker

The third device developed is intended for use in suburban and rural circuits of fairly large capacity where the advantages of fully automatic reclosing operation are desirable. In the design of this device advantage was taken of the principle of operation incorporated in the interrupter previously described as developed by the company some years ago. This interrupter had proved itself capable of interrupting fault current consistently with not over one-half-cycle arcing at the contacts and with exceptionally low arc energy, qualities essential in a breaker having over-all interrupting time (two cycles) of the order here required.

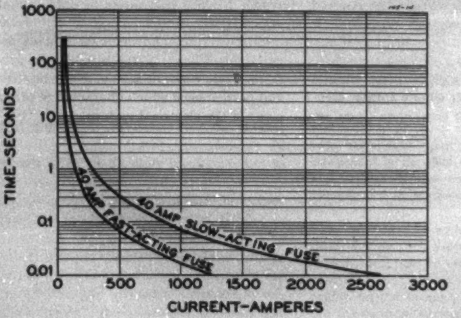

Figure 14. Characteristics of 40-ampere slow-acting and fast-acting fuses

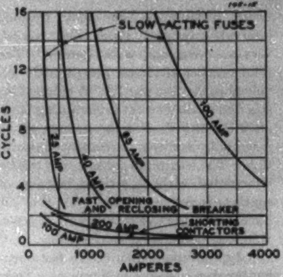

Figure 15. Characteristics of slow-acting fuses compared with switching speeds of new devices

The equipment takes the form of a single-pole, oil circuit breaker, light in weight, self-contained, and fully automatic, having its own mechanical timing mechanism. No auxiliary circuits or equipment are required for its operation. The control mechanism is arranged to give a fast initial opening followed by reclosure and a series of time-delay openings and reclosures before lockout. The mechanism resets automatically from any point in the sequence of operation, short of lockout position, upon restoration of normal circuit conditions. Units, having load-current ratings of 100 and 200 amperes, have been built for extensive trial on the Detroit Edison system. The speed of initial opening for the 100-ampere unit is shown in figure 9. It will be noted that the curve becomes flat at two-cycle over-all time and 700 amperes. These units are set to trip at 200 per cent of continuous rating. Currents up to the minimum current to operate can be carried for prolonged periods without dangerous heating.

In the latest designs the breaker will be built for load-current ratings of 100, 200, and 300 amperes with initial trip settings of 125 per cent of load-current rating.

A diagrammatic view of the device is shown in figure 10. The coil of the control relay (4) is in series with the line. In normal operation the solenoid coil (6) is shunted through switch (5). When a fault occurs, switch (5) opens and fault current flows through coil (6) which causes main contacts (9) to open. Energy stored in a spring during the opening stroke is used to reclose the breaker. In a test of one of the early experimental models of the breaker it was put through a series of complete operating cycles to lock out, at 5,000 volts, on short circuits ranging from 1,000 to 4,000 amperes. The operating cycles included initial opening followed by three time-delay operations with three-fourths second between reclosures. Time-delay tripping intervals averaged about one second, varying inversely with current. The total number of circuit interruptions involved in the test was 72. A detailed inspection of the current-interrupting parts after the test showed the breaker to be in suitable condition for continued operation. The maximum current that can be interrupted without serious burning of contacts is not known but tests thus far have shown that 7,000 amperes at 5,000 volts can be handled successfully.

A typical application of the fast-opening breaker is shown in figure 11. Only two units are required in an ungrounded system for a three-phase circuit and one unit is sufficient for a single-phase circuit. Where the advantage of one-half-cycle switching is desired in circuits equipped with the fast-opening breakers to assure against burndown of No. 6 covered wire, the shorting contactor may be added to the circuit. In an arrangement of this sort an arc will be extinguished in one-half cycle, and the artificial short circuit applied by the contactor will be removed from the system in two cycles by the breaker.

A combined plot of the burndown characteristics of covered wire and the switching speeds of the newly developed devices, all of which have been shown in earlier figures, is given in figure 12. In comparing these two sets of curves it should be remembered that the curves relating to the wires give critical values which will result in actual burndown. To hold arc damage within safe limits, the duration of arcing for given currents must be less than the values given by these curves. For rough approximation it may be said that, if arc duration is limited to about a quarter of the time shown by the burndown curve, arc damage will not be serious and the wire will retain ample mechanical strength for satisfactory continued use.

Figure 13 shows the appearance of 1,500-ampere arc burns on No. 6, No. 4, and No. 2 covered wire (*a*, *b*, and *c*) which were protected by the shorting contactor. The No. 6 wire retains 80 per cent of its original strength. The No. 2 conductor (*d*) shown in the figure was subjected to a 1,500-ampere arc which was cleared in two cycles by the fast-opening breaker. It retains 75 per cent of its original strength.

Fuses

Since the new high-speed switching devices assure the protection of fuses against operation on transient faults, the use of sectionalizing fuses may be extended without fear of creating more outages than may be avoided by their use. This new condition limits the function of fuses to clearing faulted sections or equipment in case of persistent faults only when fault current is purposely held on for a long enough period to cause them to blow. It is obvious then that fuses of the slow-acting type are more suitable with the fast switching methods than the fast-acting type. Progress made in the development of fuses with slow-acting characteristics is shown in figure 14 where the curves for 40-ampere fuses of both the fast-acting and slow-acting types are compared. Similar differences exist in other ratings. It can be seen that, for a given time to blow, the current carried by the slow-acting fuse is much greater than that for the fast-acting fuse. This means that the slow-acting type can be installed at a point in the circuit much closer to the station, where fault currents are higher, than is possible with the fast-acting type. In other words, the restrictions previously imposed upon the location of fuses are now greatly reduced. The coordination between the characteristics of slow-acting fuses and fast switching speeds of the newly developed equipment is shown in figure 15.

Conclusions

Complete interruption of distribution circuits within one-half to two cycles after fault inception will protect covered wire from burndown and unacceptable arc damage and will save fuses from operation in those cases of trouble in which the cause of fault is of transient nature. Since the line is left wholly intact, service is restored to all customers upon reclosure. Where faults prove to be persistent, the immediately following time-delay operations will blow fuses or burn the fault clear, if possible, the same as in present practice. Indications are that well over half the faults on distribution lines are of the transient type.

Several years' experience on a number of systems with so-called "instantaneous" tripping and "immediate" reclosure have disclosed no serious operating or customer problems with this pattern of operation.

Assurance against fuse operation on transient faults makes possible full realization of the potential benefits of line sectionalization.

Another advantage of high-speed initial operation is that a transient fault on one phase of a multicircuit line will not involve other phases or circuits. With prolonged arcing accompanying delayed initial operation, the rapidly increasing size of the hot gas envelope may quickly encompass the other conductors inducing further arc-overs and damage.

The addition of shorting contactors to established circuits having automatic switchgear will provide these circuits with the advantages of one-half-cycle initial interruption without major changes or expense. The addition of quick trip and immediate reclosure to the station breaker is desirable and inexpensive. The shorting contactor with its own interrupter offers a simple means for protecting a group of low-capacity circuits radiating from the station bus against failures on transient faults. The use of fast-opening and reclosing breakers on circuits that would normally be fused at the station will add to such circuits the advantages of fully automatic switchgear in addition to the benefits of two-cycle initial interruption. Single-phase switching will also reduce the number of customer interruptions.

Reducing the cases of wires down will reduce hazards and promote public good will. It will reduce outage and thereby improve service and decrease cost of repairs. It will bring the primary circuits more in line with the safety, dependability and permanence which characterize other parts of the electrical system.

Field Power-Factor Testing of Transformer Insulation and Operating Experience

E. W. WHITMER
ASSOCIATE AIEE

ONE requirement of a field test on transformers is that weaknesses which develop in bushing or winding insulation be readily located and failures prevented. This has been effectively accomplished in the American Gas and Electric Company system by a power-factor testing program of transformer insulation which was initiated in the fall of 1933. For some 18 months prior to this time, a field testing program for oil circuit-breaker insulation had been in progress. As pointed out in previous publications,[1,4] these tests had proved satisfactory particularly in locating faulty bushings and bad oil circuit-breaker insulation. It is the purpose of this paper to discuss the tests we have made on transformer winding insulation, the methods used in locating faulty conditions, and the service record of some 5,000 transformers of which 4,000 or so have been included in the test program. The tests have been useful in effectively classifying the condition of insulation thus establishing a guide for the necessary maintenance to minimize service outages. Transformer winding insulation classed unsuitable for further service has been successfully reconditioned. In a number of cases the cause of progressive faults has been detected and eliminated without need of major repairs. This procedure has helped materially in keeping equipment in first-class operating condition, in preventing failures, and in realizing substantial monetary savings.

Figure 1. Light panel delivery test car shown with back door open and power-factor test equipment in its usual position but with the high-voltage cable unreeled, ground wire connected, and in readiness for field test work

Test transformer is on floor while instrument case, writing pad, thermometers, file for test records, etc., can be seen on the shelf. The container for the high-voltage cable, shown resting on the bumper, slides into the spare tire compartment beneath the test transformer

Field Development of Tests on Transformers

Our first tests of transformer insulation were made on 200 or so 44-kv units of 500 kva or less in 1931–32. In these tests the primary object was to locate faulty bushings which at that time were disconnected from their windings and tested individually. Tests in 1933 were extended to instrument and control transformers rated 22 kv and above. In the 1933 tests bushings and windings were tested in parallel and disconnections inside the transformers were in general unnecessary particularly after improved testing methods were developed.

When the routine tests were extended to large power transformers in January 1934, it was thought, in order to locate faulty bushings, they would have to be disconnected from their windings and tested separately. This procedure was started but found unnecessary as well as slow and costly. Losses in the winding insulation were low enough so that a defective bushing might show up to some extent in most units by simply making over-all tests on the entire transformer without any internal disconnections. This procedure, of course, greatly simplified and speeded up the test work on power and distribution transformers.

At first there was considerable speculation as to whether or not faulty bushings could be consistently located by the over-all test on large transformers. During April 1934, however, some faulty bushings were located in medium size power transformers by over-all tests. Shortly after this time the manner of making the tests was changed to a method which, except for refinements, is the same as that used today. With the present high degree of development in the testing of insulation in the field, it is now seldom necessary to make any disconnections inside of transformers. It has been possible on a practical basis to individually classify the quality of the insulation of each bushing as well as that of the windings from one set of simple over-all measurements. The test methods and procedure by which this is done will be described later.

Test Equipment

The test equipment used consists of a transformer for supplying test potential up to ten kilovolt, a wattmeter, a current meter, and a voltmeter, all arranged in suitable cases and equipped with appropriate attachments. As pointed out in previous publications,[1,4] this equipment is manufactured by the Doble Engineering Company and has proved very suitable for field test work.

Paper 41-31, recommended by the AIEE standards committee, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 7, 1940; made available for preprinting December 6, 1940.

E. W. WHITMER is in the engineering department of the American Gas and Electric Service Corporation, New York, N. Y.

[1] For all numbered references, see list at end of paper.

Figure 2 (left). Field power-factor tests being made on a set of 33-kv bus potential transformers

Figure 3. Power-factor test car

Test equipment set up and ready to begin tests on a group of large power transformers at a major station

Three test outfits, each operated by an experienced test man, are now continuously used in making field power-factor tests. Figure 1 shows one of these outfits with the test equipment in the rear of a light-weight panel delivery car. Figure 2 shows tests in progress on a set of 33-kv, bus potential transformers. Figure 3 shows a test car set up and ready to start tests on a group of large power transformers at a major station. Test outfits of this kind have proved to be practical in carrying out the field work.

Test Routine

At the present time we are testing transformers, breakers, etc., about once in every $2^1/_2$ years. It normally requires approximately an hour to test a medium size bank of three or four single-phase, two-winding transformers. If faulty conditions are indicated by the normal over-all tests it occasionally becomes necessary to take readings on individual bushings or other parts, and this, of course, increases the time required to make the tests.

Equipment Tested

When routine power-factor tests were started on transformers, it was planned to test all equipment in stations operating 22 kv and above. At the present time tests are being made on practically all oil-filled transformers located in outdoor stations and operating 11 kv or above with the exception of some small isolated stations. The number of transformers tested or retested each year is approximately as follows:

1931–32	200
1933	200
1934	1,100
1935	1,000
1936	1,150
1937	1,150
1938	1,260
1939	1,400
1940 (7 months)	750

About half of these are instrument and control transformers while the others are large distribution or power units. At the time transformer tests are made, other equipment is also tested such as oil circuit breakers, underground cables, carrier-current coupling capacitors, switch sticks, sticks for hot line work, and other miscellaneous insulating parts. In general, the equipment tested is located outdoors although some indoor equipment is occasionally tested.

Table I. Typical Case of Faulty Bushing Located in a Bank of Power Transformers by Over-all Power-Factor Tests

	Over-all Tests Including Bushings and Windings			
	Other Windings Grounded		Other Windings to Shield

C	H_2	0.18	111	1.5	505

*Ten-kv values are shown although low side actually tested at 2.5 kv.

Test Methods Used

In testing a power transformer, one winding at a time is short-circuited, test voltage applied with the other winding or windings grounded. A second test is made in which the winding or windings not under test are connected to the shield circuit of the test set. These two over-all tests for each winding of large transformers have been used for the past six years although some improvements in testing procedure as well as in the test equipment have been accomplished during this period. The over-all tests for instrument or other small transformers are slightly different and were described in a previous[4] publication.

In addition to the over-all tests which are normally made on transformers, the solid types of high-voltage bushings are given a collar test. This is done by simply wrapping a suitable metal band around the porcelain near the top of the bushing and applying ten kilovolt from this band to the bushing conductor. Figure 4 shows a collar test being made on a 22-kv O.C.B. bushing. A flat spiral spring has been used to wrap around the porcelain and is simply contacted by a special fitting on the ten-kilovolt test terminal.

Interpretation of Test Results

Locating Faulty Bushings in Small Transformers

In most instrument or other small transformers, the bushings have capacitances only slightly lower than those of the windings. In making over-all tests with bushings and windings in parallel, any faulty bushings which may be present will therefore show up to about the same extent as a faulty winding. It therefore is not often difficult to determine what parts are faulty from the over-all tests. The following is a typical example of a faulty bushing located in a 33-kv instrument potential transformer.

	Microamps	Watts	Power Factor (Per Cent)
Test on bushing *A* plus bushing *B* plus winding in parallel	2,250	1.41	6.3
Test on bushing *A* with bushing *B* connected to shield	1,125	0.26	2.3
Test on bushing *B* with bushing *A* connected to shield	1,125	1.15	10.3
Test on bushing *A* removed from transformer	445	0.09	2.1
Test on bushing *B* removed from transformer	505	1.21	24.0

It will be noticed from this illustration that bushing *B* is shown to be defective by over-all test and also by those on the individual parts. When making power-factor tests on small transformers one is not likely to overlook a faulty bushing of the above nature.

Figure 4. Method of making collar test

A flat-coiled spring is wrapped around the porcelain of a 22-kv O.C.B. bushing and held in place by a special attachment on the ten-kilovolt test terminal

Locating Faulty Bushings in Large Transformers

In power and large distribution transformers, the capacitance of the windings may be many times that of a single bushing but, by careful analysis, it has been possible to determine from the over-all tests just what part if any is defective in transformers of all sizes. A system of comparisons of test values is used which, after some experience, enables the test man to determine the location of faulty parts. Table I shows a typical example of a faulty bushing located in a bank of three 2,000-kva, 22 to 2.3-kv, single-phase transformers. The over-all tests, of bushings and windings in parallel, point to a faulty high-voltage bushing in transformer *C*. This is indicated by (1) the power factor with the secondary windings connected to ground being slightly higher than that of the other two transformers, and (2) with the secondary winding connected to shield, the power factor is roughly double that of the other two transformers, while (3) the power factors on the low-voltage side of all three units are practically the same. These over-all tests therefore point to uniformity of the winding insulation and a fault in one of the high-voltage bushings of transformer *C*.

Locating Faulty Bushings by Collar Tests

The collar tests in the lower part of table I are very indicative of a fault in bushing H_1 of transformer *C* since the watts loss is considerably higher than that of the other bushings and the current value is also appreciably higher. In addition to this fault bushing *H*2 in transformer *C* as well as bushing *H*2 in transformer *B* showed slightly high collar test. An internal investigation was made which showed that bushing *H*1 in transformer *C* had a power factor of 19.3 per cent. This bushing of course was removed from service. The other two bushings having slightly high collar tests were found to have low power factors and therefore were left in service. In some of the larger power transformers the winding capacitances may be some two or three times that of units shown in table I. This of course makes it slightly more difficult to locate faulty bushings. Collar tests which were first made in our company during 1936 have proved to be very useful in helping to locate faulty bushings in transformers. By observing the over-all tests as well as the collar test, it has therefore been possible to locate bushing faults in all sizes of transformers without making any internal disconnections except in a few unusual instances.

Faults in Transformer Winding Insulation

The nature of transformer winding faults can be determined by an analysis of the test readings. In possibly 90 per cent of the transformers found to have high power-factor winding insulation, the cause has been traced to the presence of

Table II. The Effect of Different Types of Faults in Transformers Upon Power Factor and Charging Current

	Test Results				
	Before Maintenance Operation		After Maintenance Operation		
Item	Per Cent Power Factor 20 Deg C	Milliamps at 10 Kv	Per Cent Power Factor 20 Deg C	Milliamps at 10 Kv	Remarks
1	19.4	10.4	3.4	8.8	Winding dried out
2	6.8	30.6	1.6	24.5	Winding dried out
3	9.3	2.1	3.3	2.2	12.7% power factor oil replaced
4	5.5	10.6	4.2	10.5	19.2% power factor oil replaced
5	4.0	11.8	1.8	11.3	34.1% power factor bushing replaced
6	7.1	25.3	1.6	25.9	59.0% power factor bushing replaced

moisture throughout the insulation. The other ten per cent or so of transformers having high-test readings have been caused mostly by the presence of high power-factor oil. Table II shows typical test results for different types of faults in transformers. Items 1 and 2 of this table show the effect of moisture in the winding insulation. The removal of this moisture by drying not only caused a decided decrease in power factor but also an appreciable decrease in capacitance. The decreased capacitance is shown in item 1 by a decrease of from 10.4 milliamperes at 10 kv before drying to 8.8 after drying. In item 2 the decrease is from 30.6 milliamperes to 24.5 as a result of drying the winding insulation. Items 3 and 4 of this same table show the effect of replacing high power-factor oil in two transformers. It will be noticed that while there was an appreciable decrease in power factor as a result of the oil change, there is very little change in capacitance or measured current values. The presence of high power-factor oil can therefore be distinguished from a fault caused by moisture in that moisture causes an increase in capacitance and high power-factor oil does not. Separate power-factor tests can also be made on oil to determine the effect on over-all test readings.

Test experience has shown that concentrated insulation faults in the main body of transformer windings are exceedingly rare. Moisture which reaches the winding usually seems to become distributed throughout the insulation within a few months, thus causing a general rather than a concentrated fault. Bad bushings or terminal boards may, of course, be considered as concentrated faults. Referring again to table II, items 5 and 6 show the effect of bushing faults upon the over-all test readings of two typical transformers. It will be noticed that the removal of the faulty parts caused an appreciable decrease in power factor but very little difference in current or capacitance values. From such data it is apparent that any concentrated fault, while resulting in high power-factor readings, will not cause abnormally high capacitance.

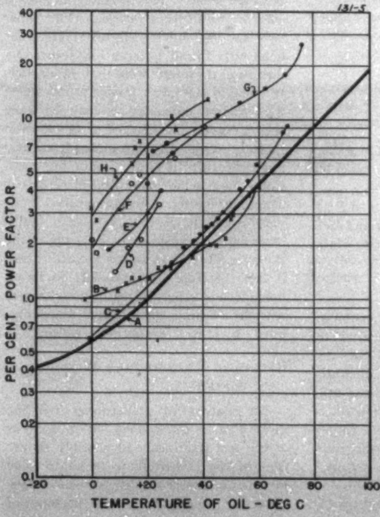

Figure 5. Temperature correction curves.

Curve *A* used in correcting power-factor readings on transformer winding insulation

Curves *B* to *H* are temperature-power factor curves run on transformers in the field and are typical of the ones from which *A* was derived

Information Obtained From Transformer Tests

From the above discussion, it is apparent that from a set of over-all readings on a transformer, collar test on the bushings, and power-factor test of its oil, one can determine:

1. The condition of each bushing to the extent of classifying its insulation.
2. The condition of the oil as far as power factor is concerned.
3. The condition of the winding insulation.
4. The general nature of faults, if any, which may exist in the winding insulation.

This affords a rather complete check of the entire insulation of the transformer.

Power-Factor Limits

Table III shows the power-factor values used in classifying transformer winding insulation. In general if the insulation is considered to be in good or satisfactory condition no maintenance recommendations are made regarding the transformer. When the winding insulation is between 3.5 and 5 per cent power factor (6 per cent for C.T. windings), the insulation is rated deteriorated. This classification is used to indicate that some fault has developed in the winding insulation but the condition is not serious enough to warrant extensive reconditioning such as drying. Transformers in this class however, are often looked over carefully in order to determine the cause of the fault which has developed in the winding insulation. Quite often faulty gasket seals are located or else the breathers may be found to be improperly located. After such minor items are taken care of, most of these transformers have given satisfac-

Table III. Power-Factor Values Used in Classifying the Condition of Transformer Winding Insulation

Classification of Winding Insulation	Power Factor in Per Cent at 20 Deg C
"G" = Good	0—3.5
"D" = Deteriorated	3.5—5*
"R" = Remove from service	Above 5*

*Six per cent power factor for current transformer windings.

tory service performance without any noticeable increase in the winding power factor for several years. Transformer windings having power factors above five per cent (six per cent for C.T.'s) are classified "remove." The cause of high power factor is usually assigned to moisture in the winding insulation. The transformers in this group are therefore generally removed from service and dried out. This treatment has in almost all instances resulted in correcting the faults as evidenced by subsequent tests.

TEMPERATURE CORRECTIONS

Since field tests on transformers are made at all times of the year and following either light or heavy loaded periods, it is necessary to apply temperature corrections to the power-factor test results for analysis purposes.

Curve *A* in figure 5 is used in converting power factor of transformer winding insulation to a base temperature of 20 degrees centigrade. Actual temperature power-factor curves run on transformers which have had considerable service in the field are shown in *B* to *H* of figure 5. These curves are typical of those from which the correction curve *A* was derived. Temperature corrections have proved practical and very useful in classifying and comparing transformer insulation by power-factor tests.

1934	11	25	16	41	0	17
1935	18	23	11	33	0	8
1938	26	17	5	22	4	8
1940	22	12	10	17	8	

TYPICAL TEST EXPERIENCE

The first transformers dried out and found to be greatly improved in power factor were in a group of some 52, 22-kv current transformers first tested in 1934. A summary of the tests made on this group of transformers from year to year is shown in table IV. The transformer cases and bushings were of an obsolete design and very difficult to make watertight, which accounts for the high percentage of winding faults. The experience with these transformers also illustrates clearly the ability of the power-factor test to indicate typical design faults in equipment. Before power-factor tests were made on these transformers, considerable trouble had been experienced, and it was thought necessary to change the oil frequently in an attempt to prevent winding failures. The first test showed some of the windings to have power factors as high as 15 to 17 per cent. Approximately one-third of the group (those with highest power factors) were removed from service and the windings dried out. Most of these windings returned to about two or three per cent power factor, which was a decided improvement. This group of current transformers (table IV) has been included in the regular testing program for some six years, and only one failure was experienced during this time. This shows that equipment found faulty by the power-factor test can be satisfactorily reconditioned.

That moisture is in many instances the cause of high power factor has been determined by field experience, but a dielectric test on oil drawn from the bottom of the case is in most instances not a reliable criterion. In fact, the dielectric tests on the oil at time of power-factor test or during previous years of service gave no noticeable indication of faulty conditions which existed in the majority of those transformers which were found to have winding insulation requiring drying. These windings when dried out returned to normal good condition as indicated by low power-factor values thus indicating that moisture was present. On the other hand, transformers in which appreciable quantities of water have been found in the oil drawn from the bottom of the tanks quite often have high power-factor winding insulation. This relation, however, is not very consistent, and obviously the best indication of moisture in the winding insulation is the magnitude of its power factor. As contrasted to the lack of correlation between dielectric of the oil and power factor of the winding, our experienced transformer men, when making winding inspections, consistently report findings of rusted spots on iron and other signs of moisture which compare very reasonably with power-factor test. Furthermore, in transformers which have high power-factor windings, a thorough inspection almost always reveals a point of very probable moisture entrance.

Operating Experience

Shown in table V are the operating and test records of some 5,000 transformers. In the table these transformers have been arranged in groups as indicated by columns 1 and 2. The service record of

**Service record from January 1, 1934 to time of first test.

each group is shown in columns 3 to 8. A direct comparison of the service performance is shown by column 5 in which is listed the number of cases of winding trouble per 1,000 transformer years of service.

This column shows that there was an average of only 1.5 cases of trouble per thousand transformer years in those windings having good insulation as judged by power-factor testing. The deteriorated transformers have almost as good a record showing only 1.7 cases of trouble. The transformers in the remove group, of course, were in most instances removed from service and reconditioned shortly after the tests were made. However, during the early stages of the test work some of these were left in service for some time, and from the table, it will be noticed that the failure record was much higher than in any other group as there was an average of 26 failures per thousand transformer years of service. In the reconditioned transformers where windings had been dried out and the units placed back in service, there has been one failure experienced or an average of 2.5 failures per thousand transformer years of service. This one failure happened to be in an obsolete type of current transformer in which difficulty was encountered in making tight moisture seals. In the service record of transformers between January 1934, and the time they were first power-factor tested, there was an average of 6.5 cases of winding trouble per thousand transformer years which was considerably higher than was experienced in transformers which tested good. In the group of transformers which has never been power-factor tested, there is an even higher rate of winding troubles as the table shows 14.7 per thousand years of service. This higher figure can be partially credited to the fact that many of these transformers are located in outlying stations and have not received as high a degree of maintenance as those in the more important stations. It so happens that a good many of these transformers are located in fairly severe lightning territory, which also probably had some effect on the troubles experienced.

The last three columns in the table show weather conditions at the time winding trouble was experienced. It will be noticed that in the group which was never tested, there was a comparatively large percentage of troubles which occurred during lightning storms. From the totals shown on the bottom line of table V it would appear, however, that more than half of the cases of trouble took place when there was no lightning.

From table V, it is apparent that transformers with high power-factor winding insulation are much more likely to fail in service than those which have low power-factor values. It is also apparent that the failure rate is appreciably higher in untested than in tested transformers, provided, of course, the transformers which test bad are removed from service or reconditioned before they have time to fail. In general, the data in table V point toward the idea that an appreciable number of transformer winding failures are the result of gradual development in the insulation of weaknesses which can be detected by periodic tests and remedied by simple reconditioning.

Table VI. Successive Tests on Two Groups of Transformers Showing the Effect of Maintenance Operations

104 Power and Distribution Transformers

	Test Rating of Winding Insulation						
	G = Good		D = Deteriorated		R = Remove		
Date Tested	No.	Per Cent	No.	Per Cent	No.	Per Cent	Remarks

1937	112	69	45	27.6	6	3.7	Oil changed in 3 transformers and 7 windings dried
1939	118	72.5	45	27.6	0	0	

Improvements in Maintenance and Operating Conditions

It is apparent that a number of failures has been prevented as a result of the power-factor testing program. While it is, of course, difficult to estimate just how many failures were prevented, it seems conservative, in the light of data such as that in table V, to say that some 100 additional cases of transformer trouble could have been expected if testing of the windings had not been undertaken some six years ago. Placing the cost of a case of winding trouble at $500, this would amount to a saving of some $50,000. Besides this, there has been an appreciable number of faulty bushings located by the test and removed from service before failure took place. By the detection and elimination of these winding and bushing faults, an appreciable number of costly failures has, no doubt, been prevented, thus minimizing interruptions to customers service.

The power-factor testing program has also created a keener interest in maintenance problems throughout the properties. So far as the insulation in bushings and transformer windings was concerned, there was no qualitative test on which the maintenance man could rely prior to the initiation of power-factor testing. For this reason, the maintenance man used to have to work in the dark so far as any accurate classification of insulation quality was concerned. The power-factor test has therefore been useful as a guide to detect the pieces of insulation requiring attention and to indicate the effectiveness of reconditioning or drying operations.

Table VI shows what was done on one property in improving the condition of transformer winding insulation. The first part of this table shows the test records on 104 power and distribution transformers, while the latter half shows the same data for 163 instrument and control transformers. It will be noticed that there is a slight increase in the number of faulty windings as indicated by the 1935 tests. There was, however, some improvement shown by the 1937 tests and a decided improvement in 1939. The increase in the number of faulty windings during the first three years or so can, no doubt, be credited to the usual rate of deterioration of winding insulation due to service conditions. The improvement shown by the 1937 and 1939 tests can be credited to the fact, that a number of transformers were overhauled and windings dried out. This improvement is especially apparent in the transformers which were classified for removal from service, since the 1939 tests did not show any windings which required servicing such as drying the insulation. These data in table VI are typical examples of what has been accomplished due to keener interest and conscientious efforts in the maintenance of insulation quality in equipment in service.

It has been possible to not only determine the nature of faults in equipment in service, but to find the cause so that recurrence of such deterioration can be prevented in the future. Likewise, the cause of minor faults has been determined and steps taken to prevent them from developing into anything of a serious nature. In this way a great deal of major maintenance such as the drying of transformer windings will, no doubt, be eliminated. It has been found that moisture frequently gets into transformers through defective gaskets under manhole or other small cover plates on the top covers of transformers. Under such plates, it has been found to be of considerable advantage to eliminate felt gaskets. The location and types of breathers on transformers have also been studied. A high percentage of faulty windings has been located in transformers where the breathers have their open ends only a few inches above the cover of transformers so that they might at times be completely covered by snow or ice. For this reason, some breathers have been relocated so as to have their open ends extend out over the edge of the top cover of the transformer. By making a few mechanical changes such as this and by eliminating defective moisture seals, we have every reason to believe that much of the equipment is more dependable and that the rate of deterioration of the insulation due to occasional entrance of moisture has been greatly decreased. The maintenance of transformer winding and bushing insulation has therefore been accomplished with a high degree of refinement which would not have been possible without a searching test like the power-factor method to indicate insulation quality and the conscientious efforts in the field to eliminate the causes of insulation deterioration.

Summary and Conclusions

From our operating and test experience with 5,000 or more transformers, and in the light of the foregoing discussion, the following conclusions can be drawn:

1. The power-factor test has proved to be very useful in classifying the quality of insulation in transformer windings as well as that of bushings and oil circuit breakers in service in the field.

2. From a simple set of over-all readings on a transformer, it is possible to determine the location of faults whether they be in the winding insulation or any one of the bushings.

3. In addition to finding the location of faults in transformer insulation it is possible to evaluate the nature or severity of deterioration that has taken place and classify the insulation as to its electrical condition for future service.

4. The power-factor test program as now being carried out on the American Gas and Electric Company system has created a keener interest in maintenance problems and therefore helped appreciably in establishing the high degree of care given to electrical equipment in the field.

5. It has been possible to locate the cause of faults indicated by power-factor test and by simple methods prevent or greatly retard the deterioration of insulation.

6. As a result of field power-factor test work, it is roughly estimated that at least 100 cases of trouble in transformer windings have been prevented at a direct saving of $50,000. By locating and correcting faulty conditions in the insulation of transformer windings, bushings, and other apparatus costly and embarrassing interruptions to customers' service have been prevented.

Shielding of Transmission Lines

Discussion and authors' closure of paper 40-107 by C. F. Wagner, G. D. McCann, and G. L. MacLane, Jr., presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 313–28.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The authors have presented their subject in such a thorough manner, and have made such exhaustive tests, that their major conclusions, with respect to the protective angle of ground wires, probably are quite correct. Their experiments and subsequent tolerances appear to check the results obtained by Matthias (references 8 and 9 of the paper).

Like all model tests of course the method adopted by the authors is based on certain assumptions. The authors prefer positive polarity because the streamers from the ground electrode have a minimum length under this condition, although it is practically certain that a majority of lightning strokes are of negative polarity. Their choice is principally based on the fact that, in photographs of natural lightning, streamers from the ground are very rarely visible, and, if they are, they are of extremely short length. In the laboratory, arcs with negative point streamers from the positive ground may reach lengths of 50 per cent or even greater of the total gap length.

Now, if the observations of the overwhelming number of negative strokes are correct, and since the photographs of natural lightning rarely show long streamers from the positive ground, quite in contrast with the laboratory experiment, then there must exist profound differences between the lightning stroke and the laboratory spark.

In the laboratory tests, we tacitly assume that not only the dimensions of the model such as cloud height, conductor height, etc., are to scale, but also the voltages. Thus, if a 40-inch gap were used with an approximate critical (minimum) sparkover voltage of 650 kv, then the voltage of a cloud at 1,000 feet is assumed to be $1{,}000 \times 12/40 \times 650$ kv or 300×650 kv $=$ 195,000 kv. We have, however, no proof that this is true, or perhaps the difference in ground streamers observed in the laboratory and from natural lightning proves that this is not true.

If the breakdown gradient required to begin streamer formation at the cloud were the same as that at the end of the rod electrode representing the cloud, then voltages of such high order could be accounted for. However, atmospheric conditions near the base of the cloud, and in the cloud, are substantially different from those near the earth's surface. Just what the gradients are at which leader formation starts is not known. However, it is easily conceivable that they are substantially lower than at the earth's surface. The leader would start then at the cloud when the gradient at the earth is still too low to cause partial breakdown of the air. As the leader progresses, the gradient at the earth's surface increases, and streamers are formed only when the leader approaches the earth electrode close enough, so that with the potential difference available between the tip of the leader and the ground electrode, phenomena as observed in the laboratory can occur. This process of reasoning is of course similar to the one used by Matthias, by which he arrived at the conclusion that the stroke path above a certain height over the ground is immaterial, and the progression of the stroke is not directed toward a definite goal until this goal is approached quite closely.

It seems that this point of view has considerable merit. It will lead probably to the most pessimistic test results if adopted for laboratory tests.

There are of course a number of other dissimilarities between natural lightning and artificial, such as availability of charges within the cloud and in the earth, and the resistance or impedance of the path through which the charges have to be conducted. None of these, however, appears to be of such importance as the actual potential scale adopted for laboratory tests and its implications.

It might be impossible to reproduce actual lightning conditions in the laboratory on a true scale, and therefore compromise tests as explained in this and other papers will probably have to be satisfactory, and the operating engineer has to choose from such tests, the operating experience and the economics of the problem how to provide the most economic shielding of the system.

H. J. Mason (General Electric Company, Pittsfield, Mass.): The question of what "cloud" polarity to use in model tests is a difficult one to answer. Two factors must be considered—first, what actually occurs in nature, and, second, the best means of simulating nature in the laboratory.

Photographs of natural lightning reveal that strokes to the open country are initiated almost entirely by downward leaders, while strokes to the tall Empire State Building are generally initiated by upward leaders. It seems reasonable to expect that there is a transition between these two extreme conditions and that upward and downward leaders of equal length might occur for structures lower than the Empire State Building. It would be very difficult to obtain a high-speed photograph of a stroke to a tall transmission line, but it might well show an upward leader of considerable length.

For this reason, then, in model tests it may not be desirable to reduce intentionally the length of upward leaders by using positive cloud polarity. Moreover, if the theory is held that the upward leader should be of negligible length, even positive polarity is not the solution for model tests, as upward leaders of one-fifth the gap length may be obtained when it is employed. For a cloud height of 1,000 feet, this would mean a leader of 200 feet.

Nor do the facts that the nature of the voltage, the weather conditions, and the scale have less effect on the distribution curves for positive than negative polarity justify the exclusive use of positive polarity in model tests. It is certainly desirable to utilize these phenomena in facilitating experimentation, but a further study of the effect of negative polarity is desirable. With negative cloud polarity a projection upon the ground plane is more attractive and is hence more difficult to protect. In the interest of conservatism this fact should not be neglected.

How to properly simulate ground resistance is also a problem in model tests. On the basis that ground resistance lowers the earth plane below the surface of the earth, Messrs. Wagner, McCann, and MacLane simulated earth resistance by an additional layer of air between the model wires and ground, presumably retaining their solid grounding. Less protection resulted.

It is well, however, to look at the problem from the standpoint of leader phenomena. When an upward leader leaves a projection on the surface of the earth, the amount of current flowing into it, and its length, may be limited by the resistance of the earth. Hence a projection on the surface of the earth where the soil resistivity is high may be less attractive than one where it is low. Tests made in the high-voltage engineering laboratory at Pittsfield support this point of view as do the tests of Messrs. Wagner, McCann, and MacLane in which they insulated the conductor instead of grounding it solidly and obtained more protection. An entirely satisfactory method of simulating ground resistance is not easy to suggest, but a layer of air does not appear to be the best solution.

E. J. Allen (General Electric Company, Pittsfield, Mass.): In this interesting paper the authors have investigated transmission-line shielding in the laboratory through the use of models, and by comparison with operating experience. Adequate shielding is obtained when the overhead ground wires are sufficiently high and properly placed so as to intercept the lightning stroke and prevent its termination on the line conductors.

Shielding is one of the basic principles of overhead ground wire protection which can be incorporated into mechanical design of a line. However, lightning flashover of shielded lines will still occur when the product of the structure footing resistance and the impulse current passing to ground exceeds the line flashover value. Because low-structure footing resistance is as powerful a factor as shielding in providing a high degree of lightning protection with overhead ground wires, its attainment in practice is essential even in the case of the higher voltage steel tower lines. For example, the exceedingly small number of insulator flashovers on the high-voltage lines considered in table II of the paper have been due not only to shielding, but to the adoption of radial or continuous counterpoises as a means of reducing tower footing resistance.[1,2]

Where the attainment of low-structure ground resistance is prevented by high-resistivity soil or rock, or by the economic dictates, protector tubes have been successfully installed to improve line performance under conditions of lightning. Several complete installations of protector tubes have been made on lines already equipped with an overhead ground wire, where the shielding angle in many cases was from 37 degrees to 55 degrees. Although these exceeded the 30-degree shielding angle suggested by the authors, protector tubes were primarily installed for a high degree of lightning protection on these lines where the existing high-tower footing resistance had prevented adequate protection by the ground wires. The protector tubes, being located in direct shunt relation to the insulators of each phase will provide lightning protection independently of the structure footing resistance.

Figure 25 of the paper shows a correlation between tower footing resistance and flashovers per 100 line miles per year for a 132-kv system. A similar correlation between protector tube operations per 100 miles per year versus tower footing resistance was prepared by Wade[3] in 1938 covering 133 miles of 132-kv steel tower line of the same system. This line has a single overhead ground wire with a shielding angle of 37 degrees to 42 degrees depending on the type of tower. The data was supported by approximately 7,700 tube-years of service experience during which records of tube operations on each phase and tower were carefully kept. It was represented by a straight line passing through 50 operations of tubes per 100 miles per year at zero tower footing resistance and 170 operations of tubes per 100 miles per year at 50 ohms tower footing resistance. The intercept at zero resistance, being at 50 operations per 100 miles per year, represents approximately four times the number of flashovers per 100 line miles per year at zero resistance shown for a similar 132-kv line in figure 25 of the paper. Whether or not this represents any significant difference depends upon whether the "flashovers" on the ordinate of figure 25 of the paper are classified as tower flashovers, circuit flashovers, or single-phase flashovers. The last should be compared with the number of tube operations.

It would be expected, as this comparison shows, that there would be more tube operations than insulator flashovers (prior to tube installations), other things being equal, because the impulse discharge voltage of the protector tubes is necessarily below the impulse flashover of the line insulators. Considering this, and since the shielding angles of the 132-kv lines being compared are practically the same, indications are that the effect of tower impedance drop and ground wire impedance for strokes at midspan is appreciable. The effect of tower surge impedance and ground wire impedance for strokes at midspan will, of course, increase with higher structures and for longer spans, as for example at river crossings.

K. B. McEachron (General Electric Company, Schenectady, N. Y.): I believe that this investigation represents a valuable contribution to our knowledge. It must be remembered, however, that these tests are subject to all of the questions which arise in connection with model tests, but because of the increased length of the discharge path compared to that used by previous investigators, the multiplying factor is reduced, and therefore one would expect the results to be more directly applicable to outdoor lightning discharges.

I would like to draw attention to a conclusion from my own work with reference to effect of polarity on the direction of propagation. I think in connection with an investigation of this sort it is essential that the conditions be kept as close as possible to those which occur in nature. Sufficient data are now available to indicate very clearly that polarity does not influence the direction of propagation to any great degree, but that the configuration of the electrodes is the determining factor. With a needle point against a plane, propagation begins at the needle point, although streamers may rise from the plane when the leader approaches close to the plane.

Our studies of lightning to the Empire State Building, together with other information which has been accumulated, indicate quite clearly that occasionally the protected zone is violated. It would appear that approximately two per cent of the strokes make contact part way down from the top on substantially vertical surfaces. I suspect that, as the height of the conducting object above the earth's surface decreases, the chance of violating the protected zone becomes less.

We have been conducting tests in Pittsfield for almost a year, following along somewhat similar lines to those reported in this paper. However, in these tests we have felt that it was essential that the polarity be kept negative, although some tests have been made with positive polarity for the purpose of exploring the field more completely. These laboratory tests, together with the photographs which we have obtained of the ground end of strokes out-of-doors, indicate quite clearly that streamers do occur from the relatively flat surface of the earth, and these streamers may be of some significance in connection with the protection offered to transmission lines by overhead ground wires.

I am rather inclined to feel that 1,000 feet does not represent an average height of storm cloud, although it may represent the lowest or nearly the lowest cloud level from which strokes occur. This is a factor on which we have some information but it is not yet in suitable form for presentation.

The authors refer to the current of the return stroke as being of the order of from 10,000 to 200,000 amperes. Data which I have indicate that the order of magnitude of the return stroke can be very much smaller—perhaps of the order of 1,000 amperes or even less.

The picture of a stroke of lightning, based on available data, seems to be one in which a current flows continuously from the time the discharge starts until it is completed, including all of the successive current peaks, which in the past may have been thought were separate identities although they did follow in the same path. It is quite certain now that a continuing current ties all of these successive discharges together. This continuing current may have values apparently as small as ten amperes or less, and the complete phenomenon of the stroke has had a measured duration as great as $1^1/_3$ seconds, although the average duration is of the order of 0.4 second.

Some idea of the protective cone as it occurs in nature may be obtained from the operation of lightning rods on protected buildings. In general, on dwelling houses or farm buildings, the vertical angle will be much greater than 60 degrees, and yet the experience where data are available indicates that such lightning rod installations are about 95 per cent effective in preventing damage to the protected buildings. As the structure becomes higher, it is necessary of course to decrease this vertical angle. It seems doubtful to me, however, if vertical angles of less than 45 degrees will in general be justified on transmission lines from an economical point of view.

S. K. Waldorf (Pennsylvania Water and Power Company, Baltimore, Md.): This paper represents the result of a careful and thorough investigation of the differences between natural and laboratory conditions of shielding. As the authors have stated, there have been inconsistencies between operating experience and the behavior predicted from model tests which have seriously reduced the usefulness of the latter. This paper does much to explain the causes of the discrepancies and points the way for making laboratory conditions better simulate nature.

It has been fortunate that at least some designs have performed better in service than could be predicted from laboratory tests. An instance of this is shown by comparison of data given in table II and figure 16 of the paper, where the performance of a 69-kv line is about six times as good as predicted. And in this connection, it is well to remember the design of a line is not based on the most severe conditions along its length, but rather on an average dictated by the designer's judgment.

There are so many factors which apparently affect the efficacy of shielding that the uninitiated may well think that finding the proper location for overhead ground wires is an almost hopeless task. However, experience shows that the situation is not nearly as bad as it seems, because operating records show that some conventional arrangements of ground wires are far more effective than the laboratory results given in this paper seem to indicate. This circumstance in no way detracts from the value of the paper. The authors' efforts help to advance the problem from the state of an art to that of a science.

W. W. Lewis (General Electric Company, Schenectady, N. Y.): The authors quote Peek's statement from his 1926 paper to the effect that for a single wire, the ground is never hit nearer the projection of the wire than about four times its height above ground.

Lewis and Foust in a paper[1] gave laboratory data which showed that with positive clouds, rods protected an area two to three times the rod height, and with negative clouds 10 to 15 times the cloud height. Hence, we have been using the figure 2 times the rod height for the radius of the protected area or two times the ground wire height for the limit of protection of the ground wire.

The authors find a protective angle of 30 degrees, after allowing proper tolerances, necessary to limit the strokes to the conductor to one per cent of the strokes to the line.

Based on operating experience on a large number of systems over a long period of years,[2] we have developed the following rule for adequate protection: For double-circuit vertically arranged lines two ground wires should be used above the conductors, one on each side of the tower and vertically above the outermost conductors. The ground wires should be at a height above the conductors approximately equal to the spacing of the conductors. For single-circuit lines horizontally arranged, two ground wires should be used, placed one on each side of the center above the conductors and on vertical planes about midway between the conductors or possibly somewhat nearer the outside conductors. The ground wires should be at a height above the conductors equal to about two-thirds of the spacing of the conductors. Thus, for the vertical arrangement the protective angle is approximately zero and for the horizontal arrangement a maximum of about 37 degrees.

On page 324 of the paper it is stated "there should be little difference between the total strokes to a line with a single or double ground wire or between a single- or double-circuit line." If I understand what this means, this is contrary to our experience. We have found double-circuit lines with one ground wire to have about 70 to 80 per cent shielding, as compared with 100 per cent shielding for double-circuit lines with two ground wires arranged in accordance with the rule stated above.[2]

C. F. Wagner, G. D. McCann, and G. L. MacLane: Most of the discussions are concerned with an analysis of the extent to which laboratory tests simulate natural lightning. Much can be written on this point without arriving at a definite conclusion. In the final analysis, the best procedure is that which was attempted in the paper which consists of comparing laboratory tests with the results of operating experiences upon actual transmission systems.

It is recognized that the similitude relations do not hold in their entirety, either with regard to the geometry of the configuration or to electrical considerations such as electric gradient or actual potentials required to produce breakdown. Mr. Hagenguth raises the question of electric similitude and in his discussion of laboratory representation of natural lightning he follows the philosophy of Matthias. Matthias arrives at the conclusion that beyond a certain cloud height or electrode height, the course of the discharge is independent of height. The laboratory tests, however, show that the distribution curves are not independent of electrode height beyond the ratio of H/h that Matthias assumes for this to be true.

Mr. Mason questions the exclusive use of positive polarity for laboratory tests on the grounds that it may not represent the true leader development of natural lightning. Even if the leader from a transmission line extends to as far as one-fifth the cloud height, which is highly improbable, the laboratory experiments with positive polarity indicate that the results are independent of the leader length, so long as this length is not exceeded. It is true that in laboratory work projections from the ground plane attract strokes from a larger area when the cloud is negative than when it is positive. This does not imply that the same condition is true for natural lightning. The upward leaders from such projections are very much greater in laboratory-produced strokes than is the case for natural lightning. The result of this condition is that the projection attracts strokes from a larger area for negative polarity than for positive polarity, but on the other hand, the result of this effect is to produce greater protection for a ground wire. Thus in terms of protection, positive polarity gives more pessimistic results.

The problem of proper representation of ground resistance as pointed out by Mr. Mason is rather complicated. Aside from the dielectric constant of the earth and the distributed voltage drops therein, this condition can be simulated by a lowering of the effective ground plane and placing a concentrated resistance as the footing resistance of the tower. In the paper the lowering of the effective ground plane was represented by an additional layer of air between the transmission conductor and true ground. Grounding both ground wire and conductor is more pessimistic than grounding only the ground wire through a resistance and permitting the conductor to be free.

Mr. Allen refers to a curve plotted by Mr. Wade which gives the number of protector tube operations as a function of tower footing resistance for the same system for which figure 25 was plotted. The data in figure 25 were obtained before the installation of protector tubes and give a flashover figure of 12 per 100 miles of line per year at zero resistance. The curve by Mr. Wade indicates 50 tube operations per 100 miles of line at zero resistance. This discrepancy may be due to the difference in definitions of flashovers and tube operations. The data obtained by Messrs. Sporn and Gross, for which Mr. Wade's curve is drawn, list the discharges of the tubes for each component of a multiple stroke as a separate tube operation, whereas only one would be indicated on the line on the basis of flashovers. It is also probable that because of the reduced insulation, more flashovers would occur on the line equipped with tubes.

Mr. Lewis recommends for double-circuit vertically arranged lines that two ground wires should be used above the conductors, one on each side of the tower and vertically above the outermost conductor. As stated in the paper, the criterion for determining ground wire location is the protective angle shaded to some extent by variations due to different values of y/h. Whether one or two ground wires be used is dependent entirely upon the most economical manner of obtaining the proper protective angle. If a protective angle of 37 degrees is satisfactory for a single-circuit line, then it should also be satisfactory for a double-circuit line. Of course, if a smaller protective angle can be obtained with very little increase in cost, which is sometimes the case, then it might be better to use the smaller angle.

There is some question in Mr. Lewis' mind regarding the statement in the paper that "there should be little difference between the total strokes to a line with a single or double ground wire, or between a single- or double-circuit line." Perhaps the paper was not sufficiently clear on this point, but the expression refers to the total strokes to the line, including those that strike the ground wire without producing an outage. In other words, the cloud area from which strokes are attracted should be about the same for a single- and a double-circuit line. This is evident from the nature of the distribution curves and has been verified by test.

The authors cannot agree entirely with Mr. McEachron's statement "that the configuration of the electrodes is the determining factor" in the direction of propagation. The laboratory tests have shown that when the point is positive with respect to a flat ground plane, the discharge propagates from the point, but when the point is negative, the discharge is initiated simultaneously from both point and plane. The authors agree with Mr. McEachron as they have stated in the paper that data relating to protective zones around tall buildings cannot be applied to smaller objects.

Since the presentation of the paper, the authors, upon further examination of Bell's* data, have discovered a misinterpretation regarding the ratio of the number of strokes that produced outages and those which produced flashovers. This ratio should be 1.5 instead of three as given in the paper. However, this does not influence the rounded value of 100 used in figure 16 for the number of strokes to lines per 100 miles of line per year.

Arcing Faults in Power Systems

Discussion and authors' closure of paper 40-106 by C. Concordia and H. A. Peterson, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 340–6.

S. B. Crary: See discussion, page 618.

P. A. Jeanne (Bell Telephone Laboratories, New York, N. Y.): The paper by Messrs. Concordia and Peterson is a useful and interesting contribution to the studies of overvoltages on power systems which have been carried on in recent years with the aid of miniature circuits in the laboratory. The usefulness of this method of analysis, as contrasted with purely mathematical analysis, is evinced by the large number of cases which it was possible to study and discuss in the present paper whereas the labor required for comparable results by mathematical analysis would have been almost prohibitive.

The uncertainty which still exists regarding the characteristics of arcs accompanying faults on operating power systems emphasizes the need for more information on this subject. While I have referred to this matter briefly in a previous discussion before the Institute, I believe it would be interest-

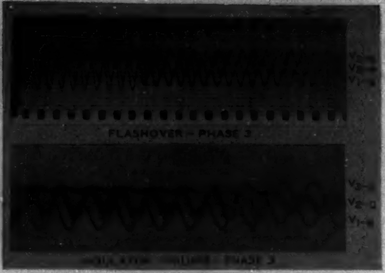

Figure 1. Oscillograms of line-to-ground voltages

ing to show a few oscillograms secured during overvoltage observations on a 550-mile, 44-kv system, which was grounded at one point through a 136-ohm neutral resistor. These data are from overvoltage studies made by the joint subcommittee on development and research, Edison Electric Institute and Bell System, with the co-operation of the American Gas and Electric Company. The first of these, figure 1 of this discussion, shows two oscillograms obtained during troubles on the power line which were correlated as being due to flashovers. The oscillograms show portions of the record before and following circuit-breaker operation. Portions of the record cut away were similar in appearance to the sections shown. The upper oscillogram was obtained with a magnetic oscillograph, and the lower one with a cathode-ray oscillograph. The important point which I wish to emphasize with these two oscillograms is the absence of any serious distortion in the sound-phase voltage waves, and the apparent absence of restriking in the faulted-phase voltage, except at the point where the breaker clears the fault. Here, in the case of the lower oscillogram, there are evidences of two restrikes in the faulted-phase voltage, presumably associated with breaker operation. The transient overvoltage peak on phase 1 resulting therefrom is clearly evident. These characteristics should be contrasted with those in the following slides. Figure 2 shows sections of two oscillograms during faults in which the arc was probably more or less restricted. The upper one, a cathode-ray oscillogram was obtained during a fault caused by cable failure. Here it will be seen that the sound-phase voltages are distorted to a considerable degree. The faulted-phase voltage waves show clearly the fact that the arc tended to extinguish and restrike every half cycle although the voltage reached before restriking was relatively low. The lower oscillogram obtained with a magnetic oscillograph is a record of fault resulting from bushing failure. Here the distortion in the sound-phase voltages is much more pronounced, and the faulted-phase voltage shows that there was restriking, sometimes only on the positive half of the cycle, sometimes only on the negative half of the cycle, the restriking voltage in practically all cases approaching approximately normal line-to-ground voltage. Figure 3 shows the neutral current of the system and the residual current on certain lines during a fault which resulted from bushing failure. The point to which I wish to draw particular attention here is the distortion in the upper or neutral current-wave trace, which indicates that there was extinction and re-establishment of the fault current. Examination of oscillograms of line-to-ground voltage and neutral current obtained during the same fault show that, as would be expected, distortions in sound-phase voltage waves are accompanied by distortion in the neutral current.

Based on these distortion criteria, an examination of the overvoltage oscillograms obtained over two lightning seasons during faults on this 44-kv system showed that most of the ones having pronounced intermediate peaks, as distinguished from initial and breaker clearing transients, were associated with bushing, transformer, or cable failure. Also, 735 neutral current oscillograms obtained over a period of about four years from this same system were examined for evidences of repeated extinction and restriking of the arc. Only 45 such oscillograms were found, and of these, 26 were definitely associated with bushing, transformer, carrier current condenser, and cable failure, while the nature of 13 of them was not definitely ascertained. Similar information on another neutral resistance-grounded system and on one extensive isolated system, seems to indicate that arcs in air seldom clear and restrike in the sense that there is an appreciable interval when the current is zero or an appreciable increase in the voltage on the faulted phase before the arc restrikes, the conditions which are requisite for the higher overvoltages in intermediate portions of a fault. The initiating or clearing transients, of course, are dependent on other factors. These conclusions are based on results from only a few systems and it may be that on some other type of system, for example, short isolated-neutral systems, a different characteristic of arcs in air might be found and it would contribute a good deal to the study of overvoltage if more data on the characteristics of arcs during faults could be obtained from operating systems.

Figure 3. Oscillogram of neutral and residual currents

I_N = neutral current
I_{R1} = residual current lines west
I_{R2} = residual current lines east

As a further tie between the miniature system tests described in the paper and observations on actual systems, the sequence constants of the 44-kv system referred to above which are required for entering the curves of figures 4 and 6 of the paper, were determined and the per-unit line-to-ground voltage which might be expected for this system, as indicated by the curves, was found to be in the order of 2.2 to 2.4 times normal, depending on the fault location, etc. Figure 4 shows the results of observations near one end of this system with both the magnetic and cathode-ray oscillograph. It is seen that a small percentage of the recorded overvoltage reached the values deduced from the curve in the Concordia-Peterson paper. Thus, a reasonably good check is shown between the maximum recorded overvoltage on this system and those indicated by the miniature system.

Additional clarification is needed on how to determine the proper constants with which to enter the curves when the system is complicated. The authors discuss this to some extent but it is not apparent just what should be done in a specific situation. For example, if, as in the case of the system I have been discussing, two main portions of the system radiate from a central large generating source, should the total positive-sequence capacitance be used, or only that up to the generating station on the side of

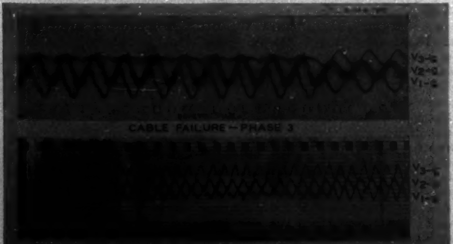

Figure 2. Oscillograms of line-to-ground voltages

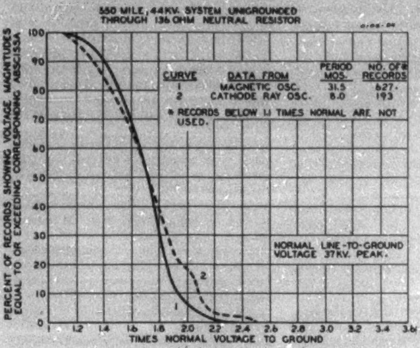

Figure 4. Cumulative percentage curves showing magnitude distribution of overvoltage

the station toward the fault, it being assumed that the capacitance beyond is shorted out by the supply source impedance? Fortunately, for resistance-grounded systems, the curves shown in the paper are relatively flat and this question is not so important. However, it would assume much more importance in the case of isolated or reactance-grounded systems. This phase of the matter may require more study.

There is one minor question as to notation. Is there any distinction intended in the use of the subscript l and L, as used in designating positive-sequence reactance on the co-ordinates of the curves and in the explanatory material, both in the paper and accompanying curves?

A. C. Monteith (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper is of particular interest to me because it gives results of investigations paralleling work we have been conducting since 1937 when the method of analysis, utilizing miniature systems was introduced at the Milwaukee convention. During the intervening time some general investigations have been carried on and a number of specific systems have been studied to determine their characteristics for arcing grounds and switching operations. As a result of this work we agree with the authors that it is better to analyze the particular system rather than depend on too great a generalization of results. This conclusion is due to the large number of variables entering into the problem. It is the complexity of the problem that has made it practically impossible to solve when approached by pure mathematical treatment.

In the paper, reference 2, which outlines some of the work done by Evans, Witzke, and myself, we chose at the time to study a particular system in order to develop a technique of handling arcing grounds and switching transients at the same time getting some ideas of the factors involved. In that particular study high values of voltage were found for reactance-grounded systems when the neutral reactance was one-third that for a ground-fault neutralizer. A review of our subsequent studies on specific systems shows a range of from $^1/_{40}$ to $^1/_8$ which agrees with the findings of the authors.

It is further noted in the conclusion of the paper that a value of five has been selected for the ratio of X_{L0}/X_{L1} as a criterion for the necessity of a study. We have suggested a ratio of 1.5 to 3 for the particular case of grounding a generator through reactance, based on limiting the voltage to 2.0 to 2.5 times line-to-neutral voltage as dictated by apparatus considerations. The limits will have a large influence on the ratio selected.

The fact that we can begin to discuss factors such as these indicates that we now have a method of attacking problems which heretofore have been too involved to attempt. This is emphasized by a case of a general study made with the a-c network calculator method involving 30 man-days work. A conservative estimate of the time to make a similar study by longhand methods indicated 25,000 man-days. With the work now in progress, in co-operation with the operating companies, it is believed much of the veiled mystery of arcing grounds, switching transients, and the like will be better understood. This should result in a better application of apparatus with better resultant system operation.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): The authors have extended the method of study begun some two years ago to try to evaluate the effect of arcing faults on power systems, and have added valuable additional information on the effects of arcing faults of different types and under different conditions on power systems of various designs.

Of particular interest is the authors' conclusion that, from the standpoint of surges and arcing faults, the solidly grounded system is definitely superior, not only to the isolated-neutral system but also to systems grounded by any other method. This conclusion is not only in accordance with the work of previous analysts but is also checked by the results of our operating experience in grounding scores of high-voltage transformers and distribution networks in the last 20 years.

Messrs. Concordia and Peterson have sounded a note of caution in connection with the use of reactors for system-neutral grounding. This confirms previous analyses and conclusions such as those contained in the reference paper of Concordia and Skeats, and is also borne out by operating experiences as described by R. A. Hentz and J. A. Adams in discussing the same paper. In this connection, as pointed out by Mr. Hentz, the use of relatively small grounding transformers for grounding systems supplied by delta-connected power transformers may in some cases produce an equivalent neutral grounding reactance well above the critical values indicated by the authors in this paper and by the curves of figure 5 in the Concordia and Skeats paper.

Our own operating experience with a few reactor-grounded systems and with a great many grounded transformer installations has so far failed to show any serious overvoltage troubles and a remarkable decrease in difficulty from what had been experienced prior to grounding. However, it is quite likely that this possibility has not been given in all cases the detailed attention it deserves when determining the sizes of grounding transformers to be used in specific applications, and in this regard the work of the authors will be most helpful.

R. L. Witzke (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In carrying out investigations of arcing faults in the laboratory by means of miniature systems it is necessary to consider a given number of restrikes of the arc. The number of restrikes required to produce a given overvoltage is of importance because as the required number of restrikes is increased, the probability of the voltage being produced is decreased. In the investigation reported by Messrs. Evans, Monteith, and Witzke in the August 1939 issue of ELECTRICAL ENGINEERING, the cases of one and two restrikes were considered. It would be of interest to know how many restrikes were required to produce the higher voltages reported in the paper under discussion.

In carrying out the investigation referred to above, we found that the method of restriking greatly influenced the transient voltages. However, until more data had been accumulated on arcing, we chose to report only restriking which resulted in the highest voltages. This gave a consistent method of attack and gave results which were valuable in comparing methods of system grounding.

An examination of figures 10 and 11 of the paper under discussion would indicate that when switching out a faulted-line section, the voltages produced are low when a ground-fault neutralizer is used. However, these voltages were obtained for the case of "interruption of a faulted conductor by a circuit-interrupting device." When the arcing occurs in series with a sound phase, the voltages produced may be higher and do not decrease when a ground-fault neutralizer is used.

Eric T. B. Gross (College of the City of New York, N. Y.): Because of my contact with the study of earth-fault problems, and especially those involved in the application of earth fault coils (ground-fault neutralizers and similar reactors, more or less exactly tuned to the capacitances-to-earth of the high-tension systems), I have found this paper very interesting, both from a theoretical and practical view. However, though everything is certainly correct from an academic point of view, in drawing conclusions, we have to find out first where the boundary lies for systems with earth-fault coils and other neutral-grounding reactors.

If we assume that the various taps of the earth-fault coils are arranged at a distance of ten per cent from each other (as is amply sufficient), we will be able to tune the coils to the capacitance-to-earth of the system with an accuracy of more than five per cent (over- or undercompensation). A change in the degree of unbalance[1] will occur only when there is a change in the capacitance-to-earth, due to the switching off of some line sections, which is not balanced by a change in tuning. It is self-evident that the installation of the coil is at such a point of the network that it will not become disconnected from the network at any time. Considering the above, we see that the degree of unbalance will never become more than five per cent undercompensation. However, it may go down in the region of overcompensation, when line sections are switched off. This means in other words that, when using an earth-fault coil, no condition will ever exist where the grounding reactance ratio X_{L0}/X_{L1} is greater than about 1.05 times the ratio for an exactly tuned earth-fault coil. We see from all the figures of the paper that such a limitation of the possible reactance of an earth-fault coil assures a reduction of possible overvoltages to the same range as obtained for "solidly" grounded neutrals. Furthermore, in the solidly grounded case, we have to consider that there will always be a certain amount of zero-sequence reactance of the grounding transformer, which acts as a neutral reactance and causes a variation of the possible overvoltages similar to that due to the various degrees of unbalance with earth-fault coil. For this reason, I would say that there is practically no physical difference between the conclusion's points 8*a* and 8*d*, and the investigation shows further that the results with the neutral grounded according to 8*c* are not only satisfactory, but practically the same as 8*a*. It should be mentioned that all this has been proved satisfactorily by experience, not only abroad but also with the earth-fault coils in this country, as is shown in the various American papers recently published on this subject.

However, there remains one fault to be mentioned,[2] in which the results of the investigations with miniature circuits[2] are only academic, as for many years the practice had followed ways to avoid any possible overvoltages when earth-fault coils were used. Earth-fault coils are installed for fundamental reasons at such points of the transmission or distribution system where no disconnection is being brought by the switching off of one or two sections. Even in the case of one double-circuit line with the coil at the energizing end of the transmission, when one circuit is switched off and de-energized, the connection between the second circuit and the coil remains, so that the remaining capacitance is by far large enough to suppress dangerous overvoltages under switching surges. Of course, it has been well known in Europe for many years that overvoltages of considerable amount could be produced when disconnecting earth-fault coil and transmission line by de-energizing the (single) line; however, in such cases, and before the modern-type overvoltage arrester had been developed, an installation was made to de-energize the line by opening the circuit breaker on the low-voltage side of the transformer. After 1929, when the modern-type overvoltage arresters (lightning arrester) with nonlinear damping resistance have been introduced in high-tension networks, such an arrester has always been used as a shunt to the earth-fault coil at the end of a single line to limit the value of the dangerous overvoltages which are otherwise possible. The arresters were of the normal type, and of the type used for systems with a line-to-line voltage equal to the star voltage of the transmission system considered. We see from this that, as far as voltage surges are concerned, there is very little difference between the performance of direct or earth-fault coil grounding, and we cannot say that one way is better than the other.

It seems to me, however, that the use of an earth-fault coil is advantageous from other points of view, one of which I would like to mention. In solidly grounding the neutral we eliminate the disastrous consequences of keeping the neutrals without any connection to earth, and especially the consequences of the capacitive earth-fault currents of arcing grounds, by introducing single-phase short circuits, i.e., we replace one very troublesome disturbance by another, less dangerous one. In both cases the number of short circuits and interruptions would be the same. On the other hand, if earth-fault coils were used, in general a great number of all ground faults would be quenched without any disturbing effect on the whole system whatsoever; in today's American practice in the use of earth-fault coils and their design, this applies only to all arcing grounds. This comparison shows undoubtedly that there are advantages in favor of the use of tuned earth-fault coils. Considering the quenching effect of the earth-fault coil, we might say with regard to this action that it is equivalent to the ultra rapidly reclosing device used in a few solidly grounded systems.

C. Concordia and **H. A. Peterson:** In regard to the discussion by Mr. Witzke, we have several comments to make. It is true that consideration of a fixed number of restrikes affords a consistent basis for carrying out an investigation. It is true also that the number of restrikes required to produce a given overvoltage is important. However, we believe that the introduction of such consistency may be undesirable since, obviously, no interrupting device is designed to produce an arbitrary number of restrikes under any and all system and fault conditions. Tests have indicated, that an interrupter may have a tendency to restrike several times for one system condition, and not at all under another.

For these reasons, we have not attempted to cling to a fixed procedure as far as the number of restrikes is concerned. Rather, the investigation was carried out with the intention of determining the maximum voltages obtainable for a variety of system conditions when restriking of a particular type occurs. In some cases it was found that a large number of restrikes would cause no serious overvoltages. In others, a few restrikes, one or two, could give rise to serious overvoltages.

The authors appreciate the comments of Dr. Gross, based upon his knowledge of system-grounding practice in Europe. It appears that the results of our investigation, and our experience in methods of grounding agree very well with modern European practice where ground-fault neutralizer coils are concerned.

As Mr. Jeanne has pointed out in his discussion, much remains to be learned about arc characteristics under actual operating conditions. It is extremely interesting to compare the limited number of available oscillograms of actual arcing phenomena with the oscillograms of similar phenomena in miniature systems. In particular, figure 2 of his discussion should be compared with figure 1 of the paper. The arcing phase voltages are quite similar in both cases.

His data summarizing overvoltage magnitudes is most helpful also in interpreting our results in terms of actual system performance. These cross checks are extremely helpful as benchmarks from which work may be continued with confidence.

As systems become more complicated, it becomes increasingly difficult to define those systems in terms of the simple impedance ratios used. As mentioned in the paper, this is particularly true of the isolated-neutral system. However, in the specific case cited by Mr. Jeanne, it would be necessary to consider the capacitance of all of the lines radiating from the bus at the large central generating source, in order to use the curves shown in the paper. In preparing these curves, there was no distinction intended in the use of the subscript *l* and *L*.

It is of interest to note from Mr. Monteith's discussion that their work paralleling ours substantiates our conclusion that the value of neutral grounding reactance giving rise to highest arcing-fault overvoltage possibilities varies through a considerable range. Our figures were from $^1/_3$ to $^1/_{30}$ the value of ground-fault neutralizer reactance while Mr. Monteith gives a range of $^1/_3$ to $^1/_{40}$.

Mr. Sporn, in summarizing the operating experience on the extensive American Gas and Electric Service Corporation systems, has further substantiated the conclusions of the authors regarding methods of system grounding. Consideration of the possibilities of overvoltages should be of particular importance in determining the size of grounding transformers for specific applications.

Mr. Crary has summarized very well the significance of the results of the numerous investigations which have been made to determine several of the fundamental sources of overvoltages in power systems. The availability of such results should be of considerable aid in system planning and designing for better performance.

Abnormal Voltage Conditions in Three-Phase Systems Produced by Single-Phase Switching

Discussion and authors' closure of paper 40-105 by Edith Clarke, H. A. Peterson, and P. H. Light, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 329–39.

E. A. Williams, Jr. (General Electric Company, Philadelphia, Pa.): The authors have presented a very able analysis of the voltage trouble which may be produced by the operation of single-pole switches and fuses on three-phase systems. The application of the outdoor, triple pole, group-operated horn-gap switch has become general practice, but the single-pole fuse is the accepted standard. Literally hundreds of thousands of single-pole fuses are giving excellent service without causing trouble due to excess system voltages. Some of the reasons for this fortunate situation may be readily deduced from the data given in the paper.

Grounded-Neutral Systems

The great majority of fuses are applied at or near the high-voltage terminals of step-down transformers and in this location are not subject to the production of abnormal voltage conditions. The relatively small percentage of fuses used for line sectionalizing and branch-line fusing rarely cause overvoltages as the existence of one or more of the following conditions results in a safe installation:

(1). The transformer neutrals are grounded.

(2). The transformers are loaded when a fuse blows.

(3). The connected transformer kilovolt-amperes exceeds the minimum required to maintain a safe ratio of x_{c1} to x_m.

An interesting analysis of conditions (3) is indicated in figure 12 of the paper. Assume a branch line, with fuses at the tap off, feeding transformers operated with ungrounded neutrals. The blowing of one or two fuses will not cause excess voltage, even under no-load conditions, provided the connected transformer kilovolt-amperes per mile exceeded that shown in the tabulation below (taken from figure 12 of the paper):

System Voltage (Kv)	Minimum Safe Kilovolt-Amperes Per Mile	
	Two Blown Fuses	One Blown Fuse
2.3	6	3
6.9	50	25
13.8	200	100
23.0	550	275
34.5	1,100	550
46.0	2,000	1,000
69.0	4,500	2,250
115.0	11,000	5,500
138.0	17,000	8,500

An inspection of this tabulation indicates that it would probably be uneconomical to build a 2.3-kv or a 6.9-kv line which would be subject to overvoltage due to single-phase switching. However, the use of branch-line fuses or sectionalizing fuses in lines above 6.9 kv, with transformer neutrals ungrounded, should be carefully checked. With the exception of this one condition, single-pole fuses may, in general, be freely and safely applied in grounded-neutral systems.

Ungrounded-Neutral Systems

The application of single-pole fuses in ungrounded-neutral systems is seldom absolutely safe from the standpoint of excess voltage. However, as pointed out by the authors in conclusion 7, the most probable cause of overvoltage is the breaking and grounding of a line conductor. This condition is entirely independent of fuse operation. The probability of the occurrence of any practical condition which would result in the blowing of only one fuse during a single line-to-ground fault seems rather remote. Therefore, it would appear that the length of line on the system side of the fuse (figure 14 of the paper) may have little bearing upon fuse applications.

Since the ratio of x_{c1} to x_m must exceed 25 to avoid excessive voltages, it may be concluded that branch-line fuses and sectionalizing fuses should not be used generally in isolated-neutral systems above 2,300 volts. With this one exception, the application of single-pole fuses in isolated-neutral systems appears to be reasonably safe from the standpoint of excess voltages.

R. D. Evans (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by Clarke, Peterson, and Light will undoubtedly raise two questions in the minds of many engineers. These questions are:

1. Do the conditions which give rise to the abnormal voltages reported in the paper also apply to the systems for which single-phase switching may be considered for improving system stability?

2. Are these abnormal voltages of frequent occurrence and of much importance from the practical standpoint?

In connection with these questions it is to be pointed out that the abnormal voltages produced by the mechanism described in the paper do not apply to three-phase systems generally but only to a very limited set of conditions. The paper may be described more precisely as dealing with abnormal voltages produced in an ungrounded section of a three-phase system which is partially isolated from a power source by means of single-phase switching. The conditions necessary for producing these abnormal voltages will not be obtained if (1) there are power sources connected to both sides of the single-phase switching equipment, or (2) if the system is solidly grounded on both sides, or (3) if the line under consideration is paralleled by another circuit. It will at once be realized that most of these exceptions will be obtained in any system for which single-phase switching would be considered for the purpose of improving system stability. More definitely, such a system would have power sources on both sides of the single-phase switching equipment, and probably also solidly grounded transformers on both sides. Thus it is clear that the conditions essential for producing abnormal voltages in the manner described in the paper are not to be expected for the ordinary layouts for which single-phase switching might be considered for improving stability. In other situations, single-phase switching may be used but if the load side is effectively grounded, then as pointed out in the paper, abnormal voltage will also not be produced.

Abnormal voltages produced by the phenomena described in the paper are, in our experience, of relatively infrequent occurrence. They do occur however for a wide range of system conditions as brought out by figures 12 and 14. The paper is of value in clarifying the conditions under which these phenomena take place and figures 12 and 14, particularly, will be of use in investigating specific cases.

S. B. Crary (General Electric Company, Schenectady, N. Y.): During the past few years, the subject of power system overvoltages due to causes other than lightning, heretofore quite neglected, has been subjected to intensive study and analysis. This work has been greatly facilitated by the use of miniature networks. This gap in the knowledge of system design and operation became increasingly apparent as the study of lightning phenomena progressed and a correspondingly increased proportion of the failures could be definitely attributed to these "other causes." From the work that has been done, exemplified by the papers of Clarke, Peterson, and Light, and Concordia and Peterson, some general remarks may be in order.

This work shows clearly that the tendency for or probability of a system having equipment damaged or service impaired by overvoltages is determined to a considerable extent by system design and operation, as well as the characteristics and design of the individual pieces of equipment. These system difficulties can be controlled to a very practical and worth-while degree in proportion to the attention given to:

(*a*). The method and details of grounding

(*b*). The proper application of lightning arresters

(*c*). The use of properly designed interrupting devices having a minimum tendency for producing overvoltages

(*d*). The correct application of single-phase switching devices

(*e*). The use of quick-acting voltage regulators for water-wheel generators in case of loss of load

(*f*). The use of properly designed amortisseur windings in water-wheel generators

One of the most outstanding results of these studies is that the highest overvoltages are almost consistently characteristic of the isolated-neutral system. This has provided much sounder reasons than previously for not operating in this manner, except possibly as a means of connecting apparatus together in a small local area which has very little possibility for faults or switching operations.

The seemingly inconsistent experience with reactor grounding has been explained and put on a more rational basis. It appears now that if reactance is to be used for grounding its value should either be very low or have a value near the ground-fault neutralizer value.

Damaging overvoltages need no longer be put aside as unexplainable or due to "surges" but should be brought out for explanation by the results obtained so far or by a transient network-analyzer study, in order that they can be better avoided in the future.

C. T. Weller (General Electric Company, Schenectady, N. Y.): Abnormal voltages unrelated to switching may be obtained with transformers on single-phase circuits under some conditions. For example, in 1915 we were testing one potential element of a 44-kv, 3-phase, 3-wire metering outfit for ratio and phase angle in the laboratory. In such single-phase tests, one primary terminal is grounded and in this case it was the outside terminal or bushing of the number 1 potential element; the "common" terminal was "high." At approximately 40 kv, an arc occurred from the outside terminal of the number 2 "unexcited" element to the nearby "high" lead. This led to an investigation and it was found that a condition of partial resonance existed between the inductance of the primary winding and its distributed capacitance to the grounded secondary winding, core, and tank. As a result, it was recommended that the installation be arranged so that the metering outfit would be permanently connected to the three-phase system.

The investigation was extended to potential transformers of various voltage ratings. Rated voltage was applied from one primary terminal to ground and it was found that considerable voltage existed across the windings in some cases; the voltage was read on the secondary. As a result, the inductance of the primary (and secondary) windings of some potential transformers was reduced, although for the usual application to three-phase systems, the line-to-ground voltage is but 58 per cent of rated voltage.

The abnormal voltage conditions described are analogous to some of those mentioned by the authors. However, I recall but one instance of such abnormal voltages on a three-phase system in practice. This occurred on a 38-kv Canadian system, when a 40-kv potential transformer was temporarily excited on one terminal; it was estimated that approximately double voltage was applied to the bus structure. While the occurrence of these abnormal voltages, both in the laboratory and in the field, fortunately appears to be infrequent, the conditions which may produce them have now been outlined. When such conditions are encountered, suitable precautions should be taken to prevent possible damage to equipment.

Edith Clarke, H. A. Peterson, and P. H. Light: The discussion by Mr. Weller indicates that the basic phenomenon giving rise to overvoltages of the type described in the paper has appeared in a variety of forms and places. Since the mechanism whereby such overvoltages may arise is basically the same for so many different circuit conditions, the quantitative data presented by the authors should be helpful in evaluating possible magnitudes of overvoltages for many conditions other than those mentioned specifically in the paper. The authors are pleased to have Mr. Weller's comments regarding his experience with overvoltage conditions of this general nature.

Mr. Williams has given an interesting and a significant interpretation of the data presented in the paper. We believe, however, that a word of caution is desirable in connection with his discussion of the grounded-neutral system. In some of the low-voltage circuits, short lengths of cable may be used. These may have a capacitance equivalent of 50 or more times the same length of overhead line (see figure 13 of the paper). It is obviously necessary to consider such cable lengths, even though they may be short, in evaluating the possible magnitudes of overvoltages.

In the ungrounded-neutral system, the probability factor, as mentioned by Mr. Williams, must be evaluated in accordance with circumstances attending a particular case. In that connection it may be desirable to consider combinations of fault and blown fuse conditions other than the one of a single line-to-ground fault and one blown fuse which was analyzed in detail in the paper. For instance, two fuses blown and a solid fault on one of the phases gives almost the same basic circuit condition. A double line-to-ground fault with two fuses blown would give a somewhat similar circuit condition. The probability of occurrence of either of these conditions may be greater than for the one analyzed. Only experience can indicate the practical significance of the analysis in this respect.

We agree with Mr. Evans' interpretation of the results of our paper. Undoubtedly single-phase switching can be used in a relatively large number of solidly grounded systems without encountering dangerous overvoltages of the type under discussion. It would seem that in such cases, the only practical limitation would be disclosed by a complete understanding of the effects of line lengths and system voltage levels from the standpoint of arc extinction time. In other words, it is likely that for a given system voltage, a practical maximum length of line exists beyond which length the arc extinction time may be prohibitively great. Even though one phase of an overhead line is open at both ends, the capacitive coupling with the other phases tends to maintain a once-established arc on that phase. This tendency is likely a function of line length, system voltage, atmospheric conditions, and possibly other factors. The practical maximum length of line probably increases as some power of the system voltage, other conditions being equal.

Linear Transformations in Three-Phase Circuits

Discussion and author's closure of paper 40-109 by Louis A. Pipes, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 351–6.

S. Austen Stigant (Messrs. Johnson and Phillips, Ltd., London, England): Dr. Pipes' application of certain established principles of matrix algebra, whereby the general nonsingular matrix may be diagonalized, to the simplification of the basic equations of the electric circuit is both useful and stimulating. The study might, I think, be extended to a formulation of rules by which the $[A]$, $[B]$, and $[Z]_t$ matrices could be written down at once for any given manner of employing the principles in question, whether in simple or in complicated cases.

An investigation of the particular equations displayed by the author discloses a somewhat simplified manner in which they may be presented, employing minors instead of the n-elements themselves.

Consider, for example, equation 68 of the paper. The principal minors and the various associated second minors of the matrix n-elements are given in table I, and it will be observed that certain of the principal minors therein appear in the various equations 69 to 82. Where indicated therefore, we may make the following substitutions.

$$= Z_{11}\left\|\begin{matrix}1, & 0, & 0\\ 0, & M_{22}, & M_{23}\\ 0, & M_{23}, & M_{33}\end{matrix}\right\| \tag{70a}$$

$$[Z]_t = Z_{11}\left\|\begin{matrix}1, & 0, & 0\\ 0, & M_{33}, & 0\\ 0, & 0, & \dfrac{M_{22}M_{33}-M_{23}^2}{M_{33}}\end{matrix}\right\| \tag{71a}$$

$$= Z_{11}\left\|\begin{matrix}1, & 0, & 0\\ 0, & M_{33}, & 0\\ 0, & 0, & \dfrac{M_1'}{M_{33}}\end{matrix}\right\| \text{or, } \frac{Z_{11}}{M_{33}}\left\|\begin{matrix}M_{33}, & 0, & 0\\ 0, & M_{33}^2, & 0\\ 0, & 0, & M_1'\end{matrix}\right\|$$

where M_1' is clearly the principal minor of the leading element in (70*a*), i.e.,

$$M_1' = M_{22}M_{33} - M_{23}^2$$

$$[A] = \frac{1}{M_{33}}\left\|\begin{matrix}M_{33}, & 0, & 0\\ -{}_pM_{33}\,{}_sM_{21}, & M_{33}, & 0\\ M_{13}, & -M_{23}, & M_{33}\end{matrix}\right\| \tag{72a}$$

$$[B] = \frac{1}{M_{33}}\left\|\begin{matrix}M_{33}, & -{}_pM_{33}\,{}_sM_{21}, & M_{13}\\ 0, & M_{33}, & -M_{23}\\ 0, & 0, & M_{33}\end{matrix}\right\| \tag{73a}$$

$$k = -\frac{M_{23}}{M_{33}} \tag{74a}$$

$$[A]^{-1} = \frac{1}{M_{33}}\left\|\begin{matrix}M_{33}, & 0, & 0\\ {}_pM_{33}\,{}_sM_{21}, & M_{33}, & 0\\ {}_sM_{21}M_{23}-M_{13}, & M_{23}, & M_{33}\end{matrix}\right\| \tag{75a}$$

$$[B]^{-1} = \frac{1}{M_{33}}\left\|\begin{matrix}M_{33}, & {}_pM_{33}\,{}_sM_{21}, & {}_sM_{21}M_{23}-M_{13}\\ 0, & M_{33}, & M_{23}\\ 0, & 0, & M_{33}\end{matrix}\right\| \tag{76a}$$

It may be noted that in (72*a*) etc., the method of expressing the n-elements in the form $-({}_pM_{33}\,{}_sM_{21})/M_{33}$ serves two purposes. The second minor ${}_sM_{21}$ (for instance) is the one giving the required element $(-n_{12})$ in the transformation matrix, but the associated principal minor ${}_pM_{33}$ shows exactly the particular second matrix from which the second minor is derived; having served that purpose ${}_pM_{33}$ is subsequently eliminated by division by M_{33}.

For the case of the general unsymmetric matrix the alternative forms are similar to the foregoing, becoming as follows:

$$[A] = \frac{1}{M_{33}}\left\|\begin{matrix}M_{33}, & 0, & 0\\ -{}_pM_{33}\,{}_sM_{12}, & M_{33}, & 0\\ M_{13}, & -M_{23}, & M_{33}\end{matrix}\right\| \tag{78a}$$

Table I

Matrix Element	Minors: Principal	Minors: Associated Seconds	Matrix Element	Minors: Principal	Minors: Associated Seconds	Matrix Element	Minors: Principal	Minors: Associated Seconds

n_{31}	${}_pM_{31}=n_{12}n_{23}-n_{13}n_{22}$	${}_sM_{12}=n_{23}$ ${}_sM_{13}=n_{22}$ ${}_sM_{22}=n_{13}$ ${}_sM_{23}=n_{12}$	n_{32}	${}_pM_{32}=I\cdot n_{23}-n_{13}n_{21}$	${}_sM_1=n_{23}$ ${}_sM_{13}=n_{21}$ ${}_sM_{21}=n_{13}$ ${}_sM_{23}=I$	n_{33}	${}_pM_{33}=I\cdot n_{22}-n_{12}n_{21}$	${}_sM_1=n_{22}$ ${}_sM_{12}=n_{21}$ ${}_sM_{21}=n_{12}$ ${}_sM_{22}=I$

$$[B]=\frac{1}{M_{33}}\begin{Vmatrix} M_{33}, & -{}_pM_{32}{}_sM_{21}, & M_{31} \\ 0, & M_{33}, & -M_{32} \\ 0, & 0, & M_{33} \end{Vmatrix} \tag{79a}$$

$$k_1=-\frac{M_{23}}{M_{33}} \tag{80a}$$

$$k_2=-\frac{M_{32}}{M_{33}} \tag{81a}$$

$$[Z]_t=Z_{11}\begin{Vmatrix} 1, & 0, & 0 \\ 0, & M_{33}, & 0 \\ 0, & 0, & \dfrac{M_{22}M_{33}-M_{23}M_{32}}{M_{33}} \end{Vmatrix} \tag{82a}$$

$$=Z_{11}\begin{Vmatrix} 1, & 0, & 0 \\ 0, & M_{33}, & 0 \\ 0, & 0, & \dfrac{M_1''}{M_{33}} \end{Vmatrix} \text{ or,}$$

$$\frac{Z_{11}}{M_{33}}\begin{Vmatrix} M_{33}, & 0, & 0 \\ 0, & M_{33}^2, & 0 \\ 0, & 0, & M_1'' \end{Vmatrix}$$

where

$$M_1''=M_{22}M_{33}-M_{23}M_{32}$$

This method of stating the matrix elements as minors of the impedance matrix (68) may lead to a more direct way of reaching the desired results. It certainly makes for co-ordination of expression.

Edward W. Kimbark (Northwestern University, Evanston, Ill.): The material in Pipes' interesting paper may be divided into two parts. One part (sections I, II, III, IV, V, and IX) treats, by matrix notation, the theory of the general linear transformation of three-phase currents, voltages, and impedances, and also treats as special cases several particular transformations, such as symmetrical components. This part is excellently done. The second part (sections VI, VII, VIII, and X) treats the diagonalization of any impedance matrix. This part is disappointing because the theory is not carried to a point where it is of value in the practical analysis of three-phase circuits.

The special transformations which have proved of value are not obtained by following the methods presented in the paper. For example, it is known that the impedance matrix of a symmetrical rotating machine (equation 6 of the paper) is diagonalized by the symmetrical component transformation (equation 22 of the paper). But the application of the method of diagonalization set forth in section VIII of the paper does not lead to symmetrical components nor to anything resembling symmetrical components.

The author seems to have overlooked the fact that a three-phase network usually contains many branches, and that a transformation which eliminates the coupling between substitutive networks in one branch only is of little or no value. What is required is a transformation that eliminates the coupling in as many branches as possible and at the same time reduces the coupling in the remaining branches to as simple a form as possible. Most branches of most three-phase networks are symmetrical and bilateral, or at least nearly enough so that they may be considered so with negligible error; that is, most branches have the type of impedance matrix given by equation 5 of the paper. It is, therefore, reasonable to demand that any transformation which is to be applied to a three-phase network should have the property of diagonalizing the impedance matrices of all symmetrical bilateral three-phase branches. Both symmetrical components and two-phase components have this property. They are not, however, the only transformations having it. Concordia[1] has given four transformations, all of which have this property.

The purpose of this discussion is to present a general transformation which does have the property of diagonalizing the impedance matrix of any symmetrical bilateral three-phase branch and which does reduce to symmetrical components and to the other transformations given by Concordia as special cases. The general transformation is as follows:

$$\left.\begin{aligned} I_{1t}&=\frac{\underline{/\theta_1}}{\sqrt{3}}(I_1+I_2+I_3)\\ I_{2t}&=\frac{\underline{/\theta_2}}{\sqrt{3}}[(\sin\phi\underline{/\theta}+\cos\phi\underline{/-\theta})I_1+\\ &\quad(a^2\sin\phi\underline{/\theta}+a\cos\phi\underline{/-\theta})I_2+\\ &\quad(a\sin\phi\underline{/\theta}+a^2\cos\phi\underline{/-\theta})I_3]\\ I_{3t}&=\frac{\underline{/\theta_3}}{\sqrt{3}}[(\cos\phi\underline{/\theta}-\sin\phi\underline{/-\theta})I_1+\\ &\quad(a^2\cos\phi\underline{/\theta}-a\sin\phi\underline{/-\theta})I_2+\\ &\quad(a\cos\phi\underline{/\theta}-a^2\sin\phi\underline{/-\theta})I_3] \end{aligned}\right\}. \tag{1}$$

This transformation is given in such form that the power is invariant; and the same transformation is to be used both for current and for voltage; consequently, the inverse transformation is the conjugate transpose of it, as follows:

$$\left.\begin{aligned} I_1&=\frac{1}{\sqrt{3}}[I_{1t}\underline{/-\theta_1}+(\sin\phi\underline{/-\theta}+\\ &\quad\cos\phi\underline{/\theta})\underline{/-\theta_2}\cdot I_{2t}+(\cos\phi\underline{/-\theta}-\\ &\quad\sin\phi\underline{/\theta})\underline{/-\theta_3}\cdot I_{3t}\\ I_2&=\frac{1}{\sqrt{3}}[I_{1t}\underline{/-\theta_1}+(a\sin\phi\underline{/-\theta}+\\ &\quad a^2\cos\phi\underline{/\theta})\underline{/-\theta_2}\cdot I_{2t}+(a\cos\phi\underline{/-\theta}-\\ &\quad a^2\sin\phi\underline{/\theta})\underline{/-\theta_3}\cdot I_{3t}\\ I_3&=\frac{1}{\sqrt{3}}[I_{1t}\underline{/-\theta_1}+(a^2\sin\phi\underline{/-\theta}+\\ &\quad a\cos\phi\underline{/\theta})\underline{/-\theta_2}\cdot I_{2t}+(a^2\cos\phi\underline{/-\theta}-\\ &\quad a\sin\phi\underline{/\theta})\underline{/-\theta_3}\cdot I_{3t} \end{aligned}\right\} \tag{2}$$

It will now be shown that the general transformation reduces to certain known special transformations. First, put $\theta_1=\theta_2=\theta_3=0$, and $\phi=0$; whence $\underline{/\theta_1}=\underline{/\theta_2}=\underline{/\theta_3}=1$, $\cos\phi=1$, and $\sin\phi=0$. The general transformation becomes:

$$\left.\begin{aligned} I_{1t}&=\frac{1}{\sqrt{3}}(I_1+I_2+I_3)=I_0\\ I_{2t}&=\frac{\underline{/-\theta}}{\sqrt{3}}(I_1+aI_2+a^2I_3)=I_+\underline{/-\theta}\\ I_{3t}&=\frac{\underline{/\theta}}{\sqrt{3}}(I_1+a^2I_2+aI_3)=I_-\underline{/\theta} \end{aligned}\right\} \tag{3}$$

which is a generalized type of symmetrical components. Putting $\theta=0$ gives the ordinary type of symmetrical components in their normalized form (power invariant). The parameter θ serves to shift the phase of reference.

Next, put $\theta_1=\theta_2=0$, $\theta_3=-90$ degrees, and $\phi=45$ degrees; whence $\underline{/\theta_1}=\underline{/\theta_2}=1$, $\underline{/\theta_3}=-j$, and $\cos\phi=\sin\phi=1/\sqrt{2}$. The result is that I_{1t} still equals I_0, while I_{2t} and I_{3t} become the direct and quadrature axis currents in normalized form:

$$\left.\begin{aligned} I_{1t}&=\frac{1}{\sqrt{3}}(I_1+I_2+I_3)=I_0\\ I_{2t}&=\sqrt{\frac{2}{3}}[\cos\theta\cdot I_1+\cos(\theta-120°)\cdot\\ &\quad I_2+\cos(\theta+120°)\cdot I_3]=I_d\\ I_{3t}&=\sqrt{\frac{2}{3}}[\sin\theta\cdot I_1+\sin(\theta-120°)\cdot\\ &\quad I_2+\sin(\theta+120°)\cdot I_3]=-I_q \end{aligned}\right\} \tag{4}$$

Again putting $\theta=0$, we get normalized two-phase components:

$$\left.\begin{aligned} I_{2t}&=\sqrt{\frac{2}{3}}\left[I_1-\frac{1}{2}(I_2+I_3)\right] \\ I_{3t}&=\frac{1}{\sqrt{2}}(-I_2+I_3) \end{aligned}\right\} \quad (5)$$

It may be shown that the general transformation (1), as well as the four special ones, diagonalizes the impedance matrix of any symmetrical bilateral branch. This general transformation may not be the *most* general one which meets the prescribed conditions, but at least it has several parameters which may be selected so as to simplify the coupling between substitutive networks. The parameters θ_1, θ_2, and θ_3 have no effect in making the transformed mutual impedances vanish; therefore, they are of little value in this study. Parameters ϕ and θ, however, may be used for this purpose.

As an example of the selection of parameters in a particular case, consider a three-phase bilateral network, all the branches of which are symmetrical except one. The one unsymmetrical branch consists of three unequal load resistances ($Z_{11}=3$, $Z_{22}=5$, $Z_{33}=10$) connected in Y with isolated neutral. Let the special transformation (4) be used. This transformation eliminates the coupling between substitutive networks of all symmetrical branches, regardless of the value of θ chosen. On account of the isolated neutral no zero-sequence current (I_{1t}) can flow in the load; and since the remainder of the three-phase network is symmetrical, there will be no current anywhere in substitute network number 1. A value of θ should be selected which eliminates the coupling between networks numbers 2 and 3 in the load branch.

By using equation 18 of the paper we find the mutual impedance between substitutive networks 2 and 3 to be:

$$Z_{23t}=\frac{\underline{/\theta_2-\theta_3}}{6}\left[Z_{11}(\underline{/-2\theta}-\underline{/2\theta})+Z_{22}\times\right.$$
$$\left.(a^2\underline{/-2\theta}-a\underline{/2\theta})+Z_{33}(a\underline{/-2\theta}-a^2\underline{/2\theta})\right] \quad (6)$$

Setting this expression equal to zero and solving for θ,

$$\underline{/4\theta}=\frac{Z_{11}+a^2Z_{22}+aZ_{33}}{Z_{11}+aZ_{22}+a^2Z_{33}} \quad (7)$$

and substituting numerical values

$$\underline{/4\theta}=\frac{3+a^25+a10}{3+a5+a^210}=\frac{-4.5+j4.3}{-4.5-j4.3}=\underline{/272.2^\circ}$$

$$4\theta=272.2^\circ\pm n360^\circ,\text{ where } n=0,\ 1,\ 2,\ 3$$
$$\theta=68^\circ,\ 158^\circ,\ 248^\circ,\text{ or }338^\circ \quad (8)$$

Putting any one of these four values of θ into equations 4 gives a transformation which completely separates networks 2 and 3. Assuming balanced electromotive forces in the three-phase network, the electromotive forces of networks 2 and 3 are in quadrature. The two networks may be solved as separate single-phase circuits, and the currents so found are combined by means of the inverse transformation to obtain the actual currents.

A general three-phase transformation has been presented, which though not the last word on the subject, appears to have more immediate usefulness than the method of diagonalization presented by Pipes. The next step should probably be a study of the number of degrees of freedom (number of independent real parameters) in the most general three-phase transformation which diagonalizes the bilateral symmetrical impedance matrix and which also keeps the power invariant.

REFERENCE

1. RELATIONS AMONG TRANSFORMATIONS USED IN ELECTRICAL ENGINEERING PROBLEMS. *General Electric Review*, volume 41, July 1938, pages 323–5.

L. A. Pipes: Professor Kimbark, in his discussion, points out that the usual three-phase network contains many branches and that transformation matrices $[A]$ and $[B]$, which diagonalize *one* individual impedance matrix, $[Z]_t$ of a branch of the network by a transformation of the form:

$$[Z]_{tt}=[A][Z]_t[B] \quad (1)$$

are of little or no practical value. He points out that most branches of such networks have impedance matrices of the completely symmetrical form:

$$[Z]_s=\begin{bmatrix} Z_0 & Z & Z \\ Z & Z_0 & Z \\ Z & Z & Z_0 \end{bmatrix} \quad (2)$$

and that therefore, matrices $[A]$ and $[B]$ must be capable of diagonalizing matrices of type (2) and at the same time reduce the other $[Z]_t$ matrices of the various branches of the network as nearly as possible to the diagonal form.

The method presented in VI of the paper, while able to diagonalize one general matrix is not capable of diagonalizing several other matrices simultaneously. In this connection, Professor Kimbark's point is well taken and he gives a special matrix that diagonalizes matrices of the type (2) and has parameters that may be adjusted to diagonalize other matrices having a limited amount of dissymmetry.

If the three-phase system has n branches of impedance matrices $[Z]_1$, $[Z]_2 \ldots [Z]_n$, the entire impedance matrix of the system is given by $[Z]$, where:

$$[Z]=\sum_{i=1}^{n}[Z]_i \quad (3)$$

The method of the paper as presented in VI, enables the general matrix $[Z]$ to be diagonalized by the transformation:

$$[Z]_t=[A][Z][B]=[A]\left(\sum_{i=1}^{n}[Z]_i\right)[B] \quad (4)$$

without diagonalizing the individual branch matrices $[Z]_i$ by transformations of the type (1).

In order to do this when the matrices $[Z]_i$ are general matrices, further research is necessary. Since the matrices $[A]$ and $[B]$ may, in the general case, contain a total of 18 *arbitrary* elements and the condition that each matrix $[Z]_i$ be diagonalized by a transformation of the form (1) leads to six equations to determine the elements of $[A]$ and $[B]$ it would appear that at most, only three matrices $[Z]_i$ of general form may be diagonalized simultaneously by the two matrices $[A]$ and $[B]$.

The matrices suggested by Professor Kimbark should prove of value in the analysis of systems having slight dissymmetry. Further research will no doubt lead to the discovery of many more matrices having utility in circuits of certain types of symmetry.

Transient Analysis of Completely Transposed Multiconductor Transmission Lines

Discussion and author's closure of paper 40-108 by Louis A. Pipes, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 346–51.

E. Weber (Polytechnic Institute of Brooklyn, N. Y.): The claim of the author that the solutions are simple is correct as far as they are presented in this paper. However, the examples given for the dissipationless as well as the general case are not of practical value on account of the special boundary conditions imposed which permit an applied voltage of arbitrary value at a certain point along the line but which assume zero current at the same point for all time. This procedure disregards entirely the boundary conditions arising from the given terminations of lines; the simple expressions obtained are, therefore, of academic value only and cannot be used in the solution of practical problems in which the terminal conditions are of utmost importance. Contrary to the author's claim, the method presented in the paper cannot in any way circumvent the well-known mathematical difficulties of transmission-line problems which are encountered in satisfying specific terminal conditions in a practical case. Furthermore, the assumption that the "entering" current i_0 be zero at all times precludes any transmission of power along the line.

It might also be of interest to consult the various papers by John R. Carson, Bell Telephone Laboratories, on the foundations of wire transmission theory.

Louis A. Pipes: Dr. Weber's contention that the boundary conditions are disregarded is well taken. However it must be emphasized that what is presented in the paper under consideration is an extension of the simple engineering formulation of the n-line problem.

This formulation of the n-line problem is based on the assumptions discussed in section II of the paper. Under these assumptions the long-line problem is regarded as a quasi-stationary field phenomenon. An admirable exposition of the present state of the theory is given by J. R. Carson's paper, "The Present Status of Wire Transmission Theory and Some of Its Outstanding Problems," *B.S.T.J.* 7, 1928, pages 268–80. What is attempted in the paper under consideration is an extension of the simplified engineering theory to the case of perfect transposition.

The use of the transformation matrix [A], separates the equations into independent sets and makes the solution formally possible. The extension of the theory to the case of "entering currents" not zero and to more general engineering boundary conditions is very simple and proceeds directly from the equations 44 and 45.

Some Characteristics and Applications of Negative-Glow Lamps

Discussion and author's closure of paper 40-110 by H. M. Ferree, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 8–12.

E. M. Strong (Cornell University, Ithaca, N. Y.): Mr. Ferree presents a timely review of the characteristics and accomplishments of the neon glow lamp family since its introduction in this country nearly a decade and a half ago.

Possibly it should be stressed that the characteristic data are average values which admit of considerable variation in individual lamps. This is of no consequence for most purposes but may be serious if one attempts to use them as oscillators or other more exacting applications. I recall making measurements when they first appeared, and considerable difficulty in finding two alike. Even for a given lamp the extinction voltage in particular is uncertain not only because of photoelectric and temperature effects but also because the discharge does not involve the entire electrode surface at near-extinction values of current, and the particular parts of the electrodes to which the discharge becomes localized vary in uncertain manner.

It seems to me that credit should be given to the neon glow lamp for bringing into existence several offspring designed for special services.

One of the most recent of these is the neon glow starting switch for fluorescent lamps. Probably the first and most important is the 885 type sweep circuit oscillator tube for the conventional cathode-ray oscillograph. Most of us readily recall the time when cathode-ray oscillographs were associated only with Lissajous figures instead of the now usual XY co-ordinates. I was studying neon lamp characteristics with Dr. Bedell at Cornell when he conceived application of the Pearson and Anson oscillator (reference 2) to provide a linear time axis for the cathode-ray oscillograph (AIEE TRANSACTIONS, volume 46, May 27, pages 546–50). I believe this was the first all-electric "sweep" provided for these oscillographs. They were marketed for some time by the Burt Laboratories in California and pioneered until a neon triode was expressly designed for the purpose. While it is impossible to detail the numerous applications which have been found for neon lamps, Doctor Bedell's contribution merits high place on the record. Doctor Reich now at the University of Illinois worked with Doctor Bedell at that time and contributed notably to the literature on neon lamp application in his own right as well as in assisting Doctor Bedell.

My first application of the lamp was for the observation of induction motor slip and synchronous motor hunting and torque angle in lecture demonstration work (*The Sibley Journal of Engineering*, December 1927, page 254). At that time only the one-fourth watt lamp had appeared. By mounting the lamp on the periphery of a small pulley attached to the machine shaft and applying terminal voltage to it, a number of traces or arcs of light equal to the poles were created, which rotated according to the slip or other deviation from synchronous speed. I still use the demonstration with refinements of bias voltage to eliminate alternate traces of light, and a peaking transformer when actual measurements are desired. Elimination of alternate traces permits its use to synchronize an alternator for connection to the station bus.

This application led to a "vector lamp" which comprises a small tabular neon lamp, at one time known to the radio trade as a "tune-a-lite," mounted as the radius of a disk rotated by a small induction type synchronous motor at 3,600 rpm. The lamp has one long and one short electrode so that the length of electrode which appears to glow is (within limits) proportional to the lamp current. When operated on 60 cycles with a peaking transformer a single line or "vector" of light appears during rotation. The length of the line is proportional to the voltage, and the angular position depends upon the phase of the voltages used to light the lamp and to drive the motor. If, for example, a transformer is operated on the same voltage as the motor, and the transformer secondary voltage is applied to the lamp, phase and magnitude changes in secondary voltage are indicated by the "light vector" as various loadings are applied to the transformer. Such demonstrations are of great help in developing early interest and confidence in vector diagrams as practical tools of the profession without demanding too much dependence on mathematical integrity.

One of the simplest applications which exploits neon lamp assets as fully as any I have devised is again a lecture demonstration device. Let us connect a resistor R and an inductance L, of suitable magnitudes in series, so that when 115 volts direct current is applied, time of the order of a second is required for the transient. If two neon lamps be connected, one across R and one across L, some acquaintance with the nature of the circuit is readily obtained. Immediately on applying voltage one electrode of the L-lamp lights; it then dims and extinguishes, and one electrode of the R-lamp lights and stays so in accord with $E = Ri + L\dfrac{di}{dt}$. If the applied electromotive force is now removed, the R-lamp promptly extinguishes and the *other* electrode of the L-lamp lights brightly and then extinguishes. Clearly the polarity of the inductive electromotive force is *reversed* during decay of current and higher magnitude is attained. Details of the entire demonstration need not be enumerated here. Similar demonstrations for simple combinations of R and C and R, L, and C are equally useful. These in no way supplant oscillographic demonstrations of greater detail but have proved of real value in introductory work.

The combined ability of the neon lamp to indicate polarity and approximate magnitude (by brightness as well as ignition and extinction voltages) without serious time lag or power absorption makes possible many applications such as the above which give it distinction as an economy instrument of considerable utility outside of its homely purpose as a low purpose illuminant.

H. M. Ferree: I feel that we are deeply indebted to Professor Strong for his enlightening discussion of our subject. The information which he has given us, and the possible new applications for negative glow lamps which he has described, has certainly done much to make this paper more interesting and profitable to all of us.

Harmonic-Current-Restrained Relays for Transformer Differential Protection

Discussion and author's closure of paper 40-87 by C. D. Hayward, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 377–82.

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): Mr. Hayward has, I believe, understated the need for an adequate relay for transformer protection. He has pointed out the solution, sometimes used with induction-type differential relays, involving high current and time settings but he has not made clear that, in many such applications, the protection afforded is little better than could be obtained with plain overcurrent relays, thus losing the advantages of sensitive and prompt action normally thought of as inherent to differential protection. Neither has he stressed the fact that the use of the various desensitizing arrangements have been accepted by most relay engineers only because there was no really adequate solution available.

The principle of harmonic restraint has already been described before the Institute. The characteristics of the magnetizing inrush have been described by many writers, so that it is a well-known fact that this phenomenon results in a current wave which is completely offset with respect to the zero axis.[1] From time to time various relay systems have been proposed which would not operate on this type of current wave, such as polarized devices requiring alternate positive and negative impulses and different filter arrangements. The harmonic-restrained relay is, however, the first device, which combines relative simplicity and a high torque, positive acting relay element, to give adequate protection against short circuits and at the same time freedom from operation on magnetizing-inrush currents.

There can be little doubt that the harmonic-restrained relay can distinguish between magnetizing-inrush currents and fault currents. There may be, to some, a question as to whether the relay will be capable of providing sufficient restraint to prevent incorrect operation on an external fault because of current-transformer errors. During the past two years considerable study has been given to current-transformer performance and as a result of these studies, the inadequacies of current transformers have been frequently discussed before the Institute. Engineers are now more conscious than ever before, of the current-transformer side of the story and, naturally, there is a tendency to consider all current transformers as of questionable performance. When we consider practical cases, however, we find that in general the current transformers used with large power transformers are capable of giving a good account of themselves under the most severe conditions to which they can be subjected. I feel, therefore, that despite the caution suggested by Mr. Hayward in the choice of current transformers, application engineers will find that the types of current transformers normally available for such applications are entirely adequate.

As a matter of record there are in service many transformer differential relays of the high-speed type having only through current restraint and operating from conventional bushing-type current transformers. Most of these use some form of desensitizing to prevent operation on magnetizing inrush, but have no special provision other than through current restraint to prevent operation on through faults. The operating record of these relays has been very good and certainly this new relay combining harmonic with through restraint should give sufficient added safety to prevent any danger of incorrect operations for most normal applications.

REFERENCE

1. TRANSFORMER ENGINEERING (a book), L. F. Blume. John Wiley and Sons, 1938.

W. K. Sonnemann and **R. M. Smith** (Westinghouse Electric and Manufacturing Company, Newark, N. J.): At first glance this paper seems to offer a solution to a problem that has long been troublesome. This problem is the one of educating a relay to distinguish between magnetizing-inrush current and short-circuit current of nearly equal magnitudes. Since the former obviously does contain harmonic components, their use in restraining the relay when operation should not occur appears logical. Unfortunately, harmonics also appear in the operating current when tripping should occur and, therefore, the relay must respond to the ratio of fundamental current to harmonic content. This would still be a satisfactory discriminating function if the ratio were always above a definite maximum value for all internal faults, and always below a definite minimum value for magnetizing inrush and external faults. It would also be desirable to have these limiting ratios subject to analysis and calculation. It has not been possible to do this because of the large number of variables involved, including the type of current-transformer design, the amount of iron, the secondary burden, the amount of current, the number of secondary turns, and the magnetic characteristics of the iron used. Possibly, however, the author has found some method of analyzing the problem which has not been included in the paper. This assumption arises from the statement that, "The harmonic-restraint curve *B* lies between the harmonic percentages obtained for the internal fault and the through fault." This would indicate an exact solution has been found. The paper would have been of greater value to the industry if this solution had been given—if such is available.

We note that the third harmonic is not available for star-delta transformers due to circulation of the third harmonic in the delta-connected current transformers. However, in reference to figure 9*D*, which is a test on a single-phase transformer, credit is given to the presence of the third-harmonic current to help desensitize the relay. From the above, we assume that the relay might well have tripped had the same test been made on a star-delta bank.

We note that the relay is restricted in its application to locations where the time constant is not greater than 0.05 second, or 3 cycles on a 60-cycle basis. We would like to inquire if this is an exact solution or if it has been arrived at from test. It would seem that other factors would also have to be specified; for example, the cross section of the iron in the current transformers would be equally important.

J. A. Elzi and **Wm. R. Brownlee** (Commonwealth and Southern Corporation, Jackson, Mich.): The desirability of a relaying system which would provide fast and sensitive protection to all types of transformer banks and connections without danger of incorrect operation on either through short circuits or magnetizing transients has long been recognized. The requirement of eliminating false tripping is particularly acute in the case of transformers since the damage which might be done to this equipment if energized after a fault is so severe that it is customary to make a thorough examination and sometimes detailed electrical tests before attempting to energize it after a differential-relay operation. Particularly in the case of transformers serving loads the operator must choose between possible extensive interruptions, overloading other equipment, or the possibility of severe damage to the transformer if it is re-energized.

The author is to be congratulated on his ingenuity in designing a device which follows so closely the characteristic which he feels is the most desirable, particularly since it is difficult to avoid transients in the various elements of devices containing tuned circuits when the external circuit is suddenly energized or changed.

In applying new principles to old problems it is frequently easier to design a device which will respond to certain quantities than it is to determine definitely the operating margins available in the conflicting characteristics of the circuit to be protected. We would like to ask if the author has made sufficient tests on other transformers to assure himself that the wave form of magnetizing inrush given in table I is closely representative.

Even if the wave form given in table I is representative, the restraint margin may not be adequate for a three-phase bank with customary connections. The author has pointed out that the third-harmonic components of through short-circuit current which are produced by the current transformers themselves may be eliminated when the current transformers are connected in delta for protecting a wye-delta transformer bank. In the same manner the third harmonics of magnetizing-inrush current in two adjacent single-phase transformers of a delta-delta bank will disappear in the common lead to the current transformers whenever the magnitude of the initial peak of two adjacent transformers are approximately equal, this being true since the fundamental components of current in the two adjacent transformers will add at 60 degrees and the third harmonics at 180 degrees. Similarly, the second harmonics of equal current peaks will be reduced with respect to the fundamental component in the ratio of 1.73 since the fundamental currents add at 60 degrees and the second harmonics at 120 degrees. The effective value of the second harmonic in the table would reduce to 36 per cent instead of 63 per cent, the third harmonic would disappear and the rms value of the second, fifth, and other harmonics would be some 50 per cent whereas the curve in figure 5 would indicate an average value of 35 per cent required for restraining operation of the relay, which may not give sufficient margin.

Reasonably good protection has been afforded by conventional ratio-differential relays to large numbers of transformers where an operating speed of four to six cycles is adequate and where a sensitivity of 50 per cent to 75 per cent of full-load current is satisfactory. Experience with over 100 such installations on the various properties of The Commonwealth and Southern Corporation has shown only four cases of difficulty due to magnetizing-inrush current, and in each of these the only difference in application has been that the power transformers themselves had normal magnetizing currents of four to six per cent of full-load current whereas many modern transformers have magnetizing currents less than $1^1/_2$ per cent. It seems likely that difficulties brought about by high normal magnetizing currents might be accentuated in the case of harmonic-restrained relays, since early saturation of the iron could account for improved wave form on the high peaks of the transient wave. Of course this assumes that customary line-current transformers would be utilized so that each relay would receive the sum at 60 degrees of the current in two adjacent single-phase transformers.

Our experience does not confirm the author's statement that it is more difficult to relay a large transformer bank. At a recent plant three transformer banks were equipped with conventional ratio-differential relays with approximately the same sensitivity and speed, one set on a 750-kva, 3-phase transformer, another on a bank of three 1,500-kva units, and a third on a bank of three 15,000-kva units. Serious difficulties with magnetizing inrush occurred on the two smaller transformers and the relay pickup had to be raised to twice full-load current to prevent frequent false operations, whereas no difficulty at all was experienced on the large bank of three 15,000-kva units with a relay pickup of 55 per cent of full load. The small transformers have magnetizing currents of four to five per cent compared with 1.14 per cent for the large bank. The

15,000-kva and the 1,500-kva transformers are energized from busses at which the system short-circuit capacities are in proportion to the transformer ratings. The respective manufacturers of these transformers have advised that the designs of the units represent their standard practice, and the relay manufacturer has stated that the relay connections, applications, etc., are also standard. Many transformers purchased during the past few years have magnetizing currents similar to the bank of three 15,000-kva units although there appears to be considerable variation between units of different manufacture purchased under the same specifications and with competitive efficiencies but without any specified limits of normal or transient magnetizing current. Consideration might be given to placing more emphasis on magnetizing-current characteristics in the purchase of major equipment and to requesting the maximum value of transient magnetizing current for comparison.

A conventional ratio-differential relay could be made to operate at relatively high speed with freedom from false operation on magnetizing transients if its sensitivity could be decreased so that it would operate only on short circuits at the power transformer terminals which would practically always be 6 to 15 times full-load current. It is well then to examine the conditions which require sensitive operation. Since plain ground relays can provide adequate sensitivity for protecting ungrounded-transformer windings where the ground current is much less than the short-circuit current, the most difficult condition normally expected is the limitation of fault current due to the nature of an internal fault in the transformer. Probably the most common occurrence is a failure on a part of the transformer winding not adjacent to the terminals so that the fault is limited by the relatively high reactance between different portions of the winding, this reactance being of such nature as to include considerable iron magnetization effect. Such a fault, both through the action of the iron involved and on account of the low current and high voltage in the resulting arc, will tend to produce harmonics of appreciable magnitude in the current wave tending to prevent correct operation. It seems that an exhaustive investigation including short-circuit tests is in order before it can be definitely determined whether or not the types of faults which require sensitive operation may defeat the apparent sensitivity of the harmonic-restrained relay. On account of the infrequency of transformer failures, particularly those other than bushing flashovers, it is doubtful if operating experience alone could provide the answer to this question except over a period of many years.

It is hoped that the sponsors of the harmonic-restraint relay will continue their study and supplement it with adequate tests to determine the performance of this type of relay under all conditions which may be encountered in the field.

C. D. Hayward: Sonnemann and Smith, in their discussion, have pointed out that a great deal of test work and analysis necessarily lies behind the selection of the amount of harmonic restraint used in the relay to insure proper restraint on magnetizing inrush and through fault-current waves, while allowing high-speed operation on internal fault-current waves. A great many tests of this kind have been made, some on actual transformer installations on operating company properties, others in the laboratories and short-circuit test stations of the General Electric Company. Analytical methods have been used to interpret, co-ordinate, and extend the results. The harmonic-restraint relay has been designed to have the characteristics dictated by these findings. Unfortunately, it is not possible to give all the details of the tests within the limited confines of a single Institute paper. Some of the tests are classed more properly under the subject of a current-transformer investigation rather than a relay investigation and will be included in a future paper under that title. In the present paper sufficient data have been given to explain the operation of the relay and to enable the relay engineer to make all ordinary applications.

Sonnemann and Smith seem to be a little confused as to the purpose of the test illustrated by the oscillogram figure 9*D*. As explained in the text of the paper, this test was made with the through-current-restraint tap plug in the minimum 15 per cent slope position for the purpose of illustrating the aiding effect of the harmonic restraint in preventing false operation on through faults. Normally, for an application where through faults of this severity are met, the tap plug would be placed in the 25 per cent or 40 per cent slope position. As Mr. Kennedy has pointed out in his discussion, there are in service today many high-speed transformer differential relays which rely on through current restraint alone to prevent operation on through faults. In the harmonic-restraint relay the double safeguard of harmonic restraint plus through current restraint is offered. True enough, as stated in the paper, where delta-connected current transformers are used, the harmonic part of the restraint will be lost on balanced three-phase through faults. But these faults are of rare occurrence and, in any case, the through current restraint is always active to prevent false tripping. Sonnemann and Smith also seem to have misread the section of the paper dealing with the selection of current transformers. The use of the harmonic-restraint relay is by no means limited to applications in which the d-c time constant does not exceed 0.05 second. The paper simply states that, as a general rule, ordinary current transformers may be used without special consideration or checking of characteristics up to a fault current value of 20 times rating if the d-c time constant does not exceed 0.05 second. The relay may be used on circuits of considerably longer time constant if the current transformers are adequate.

Elzi and Brownlee have discussed the case of magnetizing-inrush current to a delta-connected transformer bank in which, due to closing at a particular switching angle, approximately equal inrush currents are obtained in two of the three phase windings. It is quite true that, as their analysis shows, the harmonic percentages in the resultant line-current wave will be different from those shown in table I for the winding currents. In the worst case the third harmonic will be canceled; the second, fourth, and seventh reduced to 57.7 per cent of their winding values while the fifth is unchanged and the sixth is increased to 115.3 per cent. The resulting harmonic percentages in the line current then are: 36.6 per cent second, 0 per cent third, 2.9 per cent fourth, 4.1 per cent fifth, 4.3 per cent sixth, and 1.4 per cent seventh. As shown by figure 5, the harmonic percentage required to restrain the relay with normal setting is 35 per cent for the second ranging down to 25 per cent for the higher harmonics. The second harmonic would barely be able to restrain operation alone but a comfortable margin of restraint is supplied by the aid of the higher harmonics. The harmonic percentages for inrush waves taken under differing conditions will vary somewhat from those given for the typical wave in table I but the ranges are not great under conditions encountered in practice and comprehensive tests indicate that adequate restraint is always obtained with the normal harmonic-restraint setting of the relay. If a condition ever were found where the restraint was inadequate it could be readily taken care of by a slight change in the setting.

With reference to the discussion with regard to the relative severity of the magnetizing-inrush current on large transformers versus small transformers, there can be no doubt that the time duration of the magnetizing-inrush transient will be longer for large transformers than for small transformers of similar design when both are connected to power sources of sufficient capacity so that the inrush current is governed by the characteristics of the transformers rather than by those of the source. This is because the time constant of the transformer, which determines the decay rate of the inrush current, is a function of the physical size of the transformer. The magnitude of the first cycle of inrush current, measured in terms of multiples of full-load current, would be the same if the two transformers operated at the same core-flux density and were identical in other ways except physical size. It has been the general practice in years past, however, to design large power transformers to operate at higher core-flux densities than small ones, particularly where the transformer is expected to operate continuously at near full load, because of the higher full-load efficiency obtained thereby. This would mean that the large transformer, because of its higher flux density, would have a greater relative inrush current magnitude. Many factors may upset these broad conclusions, however. The impedances of the source and intervening transmission lines may limit the magnitude of the inrush current and change its rate of decay. Considerations of light-load efficiency or of limiting the magnetizing-inrush current magnitude may necessitate lower flux density. The low value of 1.14 per cent normal magnetizing current quoted for the large transformer described indicates that perhaps these latter considerations have influenced its design. Recently, some transformer purchasers, partly because of past relaying difficulties, have begun to demand low values of transient magnetizing-inrush current in their specifications. Where the relaying problem is the only one involved, it can now be solved by use of the harmonic-restraint relay and the advantages of smaller transformer size and higher full-load efficiency obtainable with the higher core-flux density design can be gained.

A High-Power Oilless Circuit Interrupter Using Water

Discussion and author's closure of paper 40-85 by W. M. Leeds, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 85–8.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): This paper describes an interesting adaptation of an idea worked on extensively by German engineers for using water as a medium of interruption in a circuit breaker. It is true that the particular model which has been constructed and which is tested and described by the author is somewhat clumsy from the standpoint of a finished design but undoubtedly a satisfactory design could, and would, be worked out if serious applications developed.

On this question, it may be of interest to go into the background leading up to the development of water breakers in Europe. There are two outstanding reasons: first, experiences abroad with the use of oil have been disappointing, if not disastrous, in some instances. This has produced a strong incentive to eliminate oil in so far as possible; second, oil itself has been a rather scarce and expensive commodity, its use being discouraged and restricted by governmental authorities.

These factors, for the most part, have not existed in this country. Further, as a result of the extensive research and development work carried out by our American manufacturers and engineers, work to which associates of the author of the paper have made significant contributions, we have had a situation where, in general, oil circuit breakers which have not been called upon to perform the impossible, always gave an excellent account of themselves.

On this question of water breakers, there is need also to point out a number of the weaknesses that these breakers may develop and some of the practical disadvantages in connection with their use. Mr. Leeds recognizes some of these:

1. There is the necessity of replacing the water in the breakers from time to time due to contamination and loss in operation.

2. The corrosive action of water on breaker parts must be taken into account and may develop unforeseen difficulties in operation.

3. The speed of these breakers does not so far compare any too favorably with that of the best oil or oil-poor circuit breaker designs. The interrupting time of from four to five cycles obtained with the experimental model as shown in table I must be compared with a speed of three cycles and under, which has been obtained readily with oil-poor and even with conventional oil circuit breakers.

I note that the author has referred to European claims that the cooling effect accompanying the sudden expansion of the steam from the operation of this breaker brings about an acceleration of the deionization in the arc space. This is a point which I discussed particularly with certain engineers in Europe some years ago, but on no occasion was I successful in discovering any definite experimental data which would substantiate this claim. I am wondering, therefore, if the author of this paper has in his own tests produced any evidence of this effect or whether he has discovered any test data from other sources which would bear out such a claim.

W. F. Skeats (General Electric Company, Philadelphia, Pa.): Mr. Leeds is to be congratulated upon the development of an experimental water circuit breaker of high interrupting capacity at 13,200 volts. The co-ordination of his contact motion is apparently well worked out and it would be interesting to have a general idea of the mechanism which has been used to accomplish this.

The water circuit breaker built by the General Electric Company was described at last summer's convention. Since that time units have been installed of both the 1,000,000-kva and 1,500,000-kva rating. The accompanying illustration shows the 1,500,000-kva 3,000-ampere breaker with cell doors and sides removed. It will be noted that there is very little external difference between this breaker and the corresponding oil circuit breaker. These breakers have closed currents with peak values reaching 118,000 amperes.

As with Mr. Leeds's breaker, distilled water is recommended, but with this breaker extreme purity is not essential, for tap water has been used for most of the tests and no trouble has been experienced either from its relatively low initial resistivity or from such further reduction as takes place as a result of circuit interruptions.

The past two years have seen the advent of water as an interrupting medium in this country and an important expansion in the application of air in this field. Both offer freedom from the fire hazard. They are competitive and one naturally wonders which will survive. The water breaker occasionally derives an advantage from better adaptation to the modernization of breakers now using oil, but for new installations, the air circuit breaker has the advantages of mechanical simplicity due to the flexibility of air operation; accessibility of the contacts for inspection—the moving contact is open to view upon opening of the cell door; and even higher current closing ability—the air circuit breaker has closed 190,000 peak amperes without any sign of distress and without visible flash.

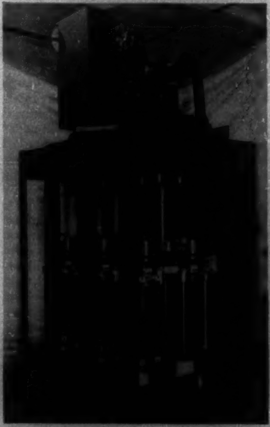

Figure 1. A 1,500,000-kva 3,000-ampere water circuit breaker

H. A. P. Langstaff (West Penn Power Company, Pittsburgh, Pa.): The design of the high-power oilless breaker as described by W. M. Leeds is very interesting especially to central station engineers. He frankly points out factors which give rise to questions of a practical nature. He states that the device does not fulfill the requirements of an ideal breaker, being subject to contamination and loss of water. There also is mentioned the possibility of corrosion of metal parts and of deterioration of the insulation exposed to water or steam. Mr. Leeds hopefully expresses the opinion that these problems are not insuperable, but to me it seems quite evident that considerable work and design will be required to make this type of breaker acceptable for American operating practices.

The paper gives no information as to the means of adding water or of finding out when water is needed. Mr. Leeds states that from four to six short circuits in the range of from 50 to 60,000 amperes can be interrupted without changing the water and that 100 or more low- or medium-current interruptions can be made before the resistivity of the water is such as to require water replacement. Mention is made that the distilled water put into the interrupter usually measures about 100,000 ohms per centimeter. No data is given as to the allowable range of water resistivity to qualify the water for use in the interrupter.

It would be interesting to know how soon the breaker may be reclosed upon a fault after interrupting a fault. Figures 6 and 7 of the paper show oscillographs taken when closing the breaker upon a fault of comparatively low ampere value. It would be interesting to see the same curves for the breaker operating with the 60,000-ampere current range such as illustrated in figures 8 and 9 for the opening operation only. In testing such a breaker to destruction, the question naturally arises as to how it would compare with an oil circuit breaker of the same rating.

The paper states that the closing of high currents on the air-disconnect-switch contacts is accomplished with very little arcing due to the high-speed snap action. It would also be interesting to know the speed of all three closing actions; namely, arcing contacts in water, series disconnect switch, and the main closing switch. I assume it would also be necessary periodically to determine the resistance of the water in the breaker somewhat the same as the making of oil tests. It is noted that practically all of the parts to which the water is exposed are of nonrusting materials but these may affect the water and I assume the manufacturer has some information already available on this as a result of the tests.

The comparative costs of this type of

breaker as compared with one of present-day design I assume to be identical for the same respective ratings in view of the fact that it seems that present day prices are based on rupturing capacity.

In general it may be stated that a high-capacity breaker without oil is a very attractive piece of apparatus. This development can be classified as a step in the direction of that attainment.

R. C. Van Sickle (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The development reported by Mr. Leeds has an interesting relation to the development of earlier water breakers.

The European water breakers were introduced almost ten years ago for services of 6 kv and 10 kv and for interrupting capacities up to 400,000 kva. Since then, the range of interrupting capacity has been raised gradually to 600,000 kva and 800,000 kva at 10 kv.

During this period, our demands for oilless breakers at corresponding American voltages were met by the "de-ion" air circuit breakers of comparable interrupting capacity.

To meet demands for higher interrupting capacity, the investigations reported by Mr. Leeds were made. Consequently this development instead of starting at moderate capacities and expanding into the higher and lower ranges, took advantage of the earlier work of the German designers of "expansion" water breakers and applied it to a breaker for approximately double the interrupting capacity of other competitive types of oilless breakers. This emphasizes the magnitude of the problems and the significance of the work described.

D. C. Prince (General Electric Company, Schenectady, N. Y.): In this very interesting paper, the author expresses the view that the "expansion theory" proposed for the water circuit breaker on the continent has not been sufficiently supported by critical evidence. Instead of that theory, he suggests that the arc is subjected to a "turbulent blast tending to sweep the arc products downward and away from the contact tip". It will be noted that this represents an agreement with our often repeated contention that displacement of arc products by an unimpaired dielectric is the predominant instrumentality in the operation of many circuit breakers.

The author mentions "heavy, local pressures". It would be interesting to know just how heavy these local pressures are and whether the safety valve mechanism employed to control them is effective in keeping the pressures uniform over a wide range of interrupting currents. It is interesting to compare this method of controlling the pressure with that employed by W. F. Skeats in his hydro-blast breaker described before the summer convention of the American Institute a year ago (High-Capacity Hydro-Blast Circuit Breaker for Central Station Service, AIEE TRANSACTIONS, 1940, pages 111–16). Skeats employs a very ingenious arc control device to determine pressure generated in contradistinction to the device described by the author, which merely attempts to prevent the increased evolution at high currents from having destructive effects. A side light on this question is that the Leeds breaker is provided with a steam condensing chamber from which some steam escapes under heavy load (as high as 10 per cent according to the author), whereas the Skeats breaker requires no vent.

Hydro-blast breakers up to 1,500,000 kva are now in service. It would be interesting to know whether a service record is also being obtained for the circuit breaker described in this paper.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In 1918 the writer participated in interrupting tests at 11,000 volts using water in metal tanks that were insulated from ground. At that period, however, the problem before switchgear designers was to secure adequacy of interruption regardless of the medium, and since oil was definitely superior from an insulating view the water development was not pushed.

About 1928 water was taken up seriously in Germany as a substitute for oil in circuit interrupters and a great commercial activity has been developed in that country, particularly by Siemens-Schuckert, for voltages up to 60 kv indoor. A limitation in rupturing capacities at the lower voltages has made the European device unattractive in this country. About 600,000 kva at 15 kv has been used commercially and we understand later developments are good for 800,000 kva at the same voltage. Higher voltages permit some increase of capacity.

The paper by Mr. Leeds outlines the work done to push the interrupting capacity for powerhouse voltages to the point necessary for American service and we believe there is no doubt that 1,500,000 kva can be handled at from 12 to 15 kv satisfactorily with the type described in the paper.

As is universal with devices generating gas for arc extinction, the arcing time is somewhat longer than if a separate source of pressure were used. However, the overall interrupting times, from 3.2 to 5.1 cycles on a 60-cycle basis, are lower than with conventional apparatus and compare favorably with compressed air.

This type of device must generate enough gas pressure at low currents to secure interruption and the physical limit therefore is the pressure which can be withstood under high-current conditions. The materials available for the pressure chamber are fibrous in character and their insulating quality under water must be carefully watched.

An interesting feature is the lack of external ventilating pipes and expansion chambers since the gases formed from water are not permanent and the necessary expansion effect can be taken care of in the mechanism box shown in figure 5 of the paper.

For the usual switch service maintenance of the water is not difficult and various antifreeze compounds have been developed permitting use in low temperatures. These detract slightly from the interrupting ability.

The principal advantage of the water interrupter, in addition to the fact that the liquid is noninflammable, is that it is self-contained and does not require auxiliary equipment, therefore, it can be located conveniently in small groups such as required in station auxiliary layouts and small substations.

R. A. Hentz (Philadelphia Electric Company, Philadelphia, Pa.): The many advantages of the oilless type breaker over the oil type, in spite of a reasonably good performance on the part of the latter, well justify the thought, research, and development that has been given to the various oilless types by the several manufacturers. The trend was started over ten years ago with the development of the air deion circuit breaker, but unfortunately on account of the depression further progress in the general direction of doing away with oil was very slow until the last two or three years.

The type breaker as represented by the air deion has advantages over those requiring the use of compressed air or water, but unfortunately they cannot be developed in the higher interrupting ratings and consequently circuit breaker engineers have had to resort to the use of these other schemes.

Both compressed air and water have been used in Europe and it is unproved which of these two will ultimately be shown to be the most desirable for indoor service in this country. The trend appears to be definitely toward the airblast type, but sufficient operating experience is lacking, though I believe that such difficulties that are met with can be solved satisfactorily.

On the other hand, experience with fifteen breakers in service, the first ones for nearly two years, leads me to conclude that there is no fundamental drawback in the water breaker. Based on the successful experience of the first six that were installed on the Philadelphia Electric Company system experimentally, that company has placed orders for nineteen additional breakers ranging in interrupting rating from 500,000 to 1,500,000 kva and of ampere carrying capacities up as high as 3,000 amperes.

The water breaker covered by Mr. Leeds's paper appears to be well designed and the tests shown in his table II, as well as the oscillographs, show that the breaker can adequately interrupt both heavy and light short-circuit currents. However, like any new development, the day-in and day-out experiences with it under all kinds of operating conditions are necessary before the breaker can have general acceptance. As pointed out above the experience with a water breaker of a different manufacture than that of the company with which Mr. Leeds is connected has shown no fundamental difficulty and it is unfortunate that similar experience is not available on the water breaker that Mr. Leeds described.

In closing I wish to express my concurrence with Mr. Leeds's conclusions.

W. M. Leeds: Mr. Langstaff's doubt that water breaker designs are acceptable for American operating practice because of possible corrosion or insulation difficulties is apparently not shared by Mr. Hentz who seems to have obtained satisfactory service from one type of water breaker. That is not to say, however, that there may not be valid reasons for believing other types of interrupters to have preferable characteristics, but the many years of successful operation in Europe of water breakers in low and medium interrupting ratings as well as the more recent demonstrations of ability to meet heavy duty service requirements seem at least to merit serious consideration for this type of oil less circuit breaker.

A glass water-level gauge, not shown in figure 2 of the paper, is used to determine when water should be added, such water being poured in through the opening under the hinged cover *E*, figure 5. Small drain holes allow this water to reach the interrupting chamber in the same way that condensed steam and water vapor is returned.

By using a series disconnecting switch to remove potential from the water chamber, and by completing the circuit in air during closing operations, the most serious hazards of low dielectric strength water have been avoided. Successful interruption can be obtained with a water resistivity as low as 1,000 ohm-cm, but it has been our practice to use pure distilled water, and keep the resistivity between 10,000 and 100,000 ohm-cm.

Mr. Langstaff also asks how soon the breaker may be reclosed on a fault after interrupting a fault. We have found nothing in our testing which would prevent the use of the water breaker on rapid reclosing duty cycles, applying the same derating factors now standard for oil circuit breakers.

It should be pointed out that the oscillogram of figure 7 of the paper shows a close-open operation on the same circuit that gave approximately 60,000 amperes on the opening tests of figures 8 and 9. The first cycle rms current for figure 7 was 55,000 amperes, the current wave not being completely displaced. The low value of 29,000 amperes for the interrupted current is due, of course, to the decrement during six cycles of short circuit.

When the water breaker is tested to the point of failure, a blowout patch on the vent channel to the mechanism box comes off, allowing steam and water to blow out; and also an open arc is drawn by the disconnect switch. This all subsides at once as soon as the short circuit is opened by the back-up breaker.

The question of the mechanical closing speed has been raised. The arcing contacts in the water chamber close at approximately 10 feet per second, the series disconnect or closing switch at 20 feet per second, and the main paralleling switch at about 5 feet per second.

In investigating possible corrosive effects of distilled water on the various metallic and fibrous materials used in the water breaker no evidence of water contamination was noted, although this might not be the case with certain kinds of tap water.

It is of particular interest to note from Mr. Hentz's discussion that after two years of experience with water breakers, he is led to conclude that "there is no fundamental drawback in the water breaker". Many hundreds of water breakers have been put in service abroad, principally by the Siemens-Schuckert Company. We have had the opportunity to follow this field experience, and have reached somewhat the same conclusion as Mr. Hentz. Additional service experience in this country is not contemplated, however, unless present conditions regarding the demand for water breakers should change materially.

In answer to Mr. Skeats's request for more complete information on the breaker operating mechanism, the accompanying illustration is shown, giving the schematic arrangement. The air disconnecting switch is operated by an over-center toggle spring action controlled by latches that are released just before the end of the operating arm motion on both the closing and opening sequences. Knocking rollers strike the switch arm to make the action positive.

With regard to Mr. Prince's interpretation of the arc interruption in the water breaker in terms of his "displacement theory", we should like to point out that even without the water flow arrangement provided in the final design, practically the full rating of the breaker has been successfully interrupted with only turbulence and diffusion effects present. However, the directive effect of this longitudinal flow which moves liquid up to the moving arcing contact tip was found to increase the effectiveness of the diffusion process so that the arcing time could be appreciably shortened.

Figure 2. Water breaker operating mechanism; left, open; right, closed

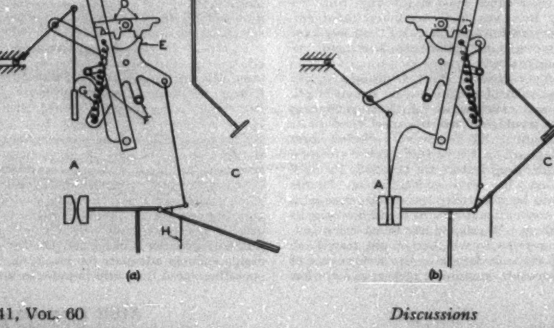
H. Operating rod to solenoid mechanism



While it was not found practical to locate pressure recording devices in the central arcing chamber, certain calculations based on the resistance of the rubber retaining ring and the yield point of certain clamping bolts which were later replaced by a stronger design indicate pressures of approximately 50 pounds per square inch for low current interruptions up to instantaneous peak values approaching 1,000 pounds per square inch at the breaker rating.

Whether or not a specific vent is provided on a water breaker, such permanent gases as hydrogen and carbon monoxide which are mixed with the steam and water vapor must eventually find their way out. The design of water described in the paper has a large condensation chamber and a screened and baffled passage to a vent, so that pressure is rapidly lowered to be ready for the next operation, and yet no connection to an exhaust header is necessary.

Mr. Sporn asks whether we have discovered any experimental evidence to substantiate the European claims that arc extinction in water breakers is due to the cooling effect accompanying sudden expansion of steam. It is evident that in the German "expansion breaker" that expansion does take place and that the arc is extinguished, but the importance of the contribution to de-ionization of the cooling effect does not appear to be quantitatively proved. It is interesting to note in the article by F. Kesselring, "The Expansion Breaker" (*V. D. I.*, volume 78, March 1934, pages 293–7) that emphasis is given to deionization by diffusion in a hydrogen atmosphere as one of the most important factors in the interrupting process.

Medium-Capacity Air-Blast Circuit Breakers for Metal-Clad Switchgear

Discussion and authors' closure of paper 40-125 by R. M. Bennett and B. W. Wyman, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 383–8.

Joseph Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The theory of arc extinction in the cross-blast breaker given by the present authors is substantially that advocated by Prince, Henley, and Rankin in their paper presented at the winter convention. This theory is beautifully simple, and leads to a beautifully simple equation.

According to this simple theory, at current zero, the arc column just naturally of itself falls apart at one or more points, thus forming several disconnected pieces. These disconnected pieces then separate from each other with a speed given by the gas velocity. The simple theory does not go into any detail as to the mechanism whereby the arc column is broken into two or more disconnected pieces. Apparently, this mechanism does not require any great gas velocity, since Prince, Henley, and Rankin only require that the gas velocity be great enough to interpose fresh gas between the already separated arc column fragments fast enough so that the rising circuit voltage may be withheld.

The present authors modify the Prince, Henley, and Rankin theory, and make it less simple. The falling apart of the arc column at current zero into distinct pieces no longer just naturally takes place of itself, but must be preceded by the formation of a loop, with considerable gas volume required. Just why the forming of a loop is necessary to make the arc column fall apart is not made very clear. No loop forms in the longitudinal oil-blast and gas-blast breakers, and yet Prince and Skeats, and Prince, Henley, and Rankin do not hesitate to apply their simple theory to these cases.

For a given air blast, to obtain interruption according to their theory, the authors state that the current must not be so large as to prevent loop formation. However, in figure 6, currents as low as 1,200 and 2,100 amperes also gave poorer operation than their theory predicted, so that the annoying question comes up as to whether loop formation failed to occur even for a current as small as 1,200 amperes.

The picture of the arc column blown into loops prior to current zero, shown in figure 4, raises some strong questions as to the possibility of other factors being responsible for the arc extinction than the physical cutting of the arc required by the authors' theory. Figure 4 shows considerable lengths of the arc pushed into small cross section up against the barrier walls. Will not these lengths of arc column have very considerable circuit-interrupting capacity in themselves, particularly since they lie in a region of high turbulence occasioned by the mixing with the main blast of the gas emitted from the barriers?

I would like to ask the authors whether they believe that the translatory velocity next to the barrier surfaces, where they place the arc column, is small or large compared to the main-blast velocity. If it is small, what has become of their theory? Aerodynamists agree in permitting only a small translatory velocity next to a fixed bounding surface.

I would like to ask the authors whether they believe that the gas evolved by the barriers, plays no part at all in the circuit interruption. What success have they had with nongas-forming barriers, or barriers which give less gas than the fiber barriers actually used?

Lastly, in all other breakers, magnetic effects quickly blow large current arcs out to much greater lengths than the actual contact separation. Does not this take place in this breaker? If so, how do they then account for their figure 5, showing contact separation, and not arc length as independent of current for a given circuit-recovery rate?

J. R. North (The Commonwealth and Southern Corporation, Jackson, Mich.): Our companies, along with many others, are keenly interested in the various forms of new oilless circuit breakers and some of our recent 2,400-volt installations are composed of air circuit breakers. Air breakers, both the self-contained units and the blast type of air breaker appear to be particularly promising from the standpoint of

(*a*). Ease of inspection and maintenance,

(*b*). Probable greater inherent interrupting ability on repetitive reclosing duty cycles,

(*c*). Compactness,

(*d*). Elimination of oil in indoor units (despite our reasonably satisfactory operating experience with oil breakers in general).

The papers presented at this and at other Institute meetings are very interesting and have shown some features of these new developments of circuit-interrupting devices, the results of interrupting tests, and structural arrangements. However, judging from experience in applying oilless breakers, it appears that there is a dearth of information concerning the durability of some parts of the arc-interrupting devices and the operating performance which may be expected in service. We should therefore urge the manufacturers to give more thought to the following matters in connection with all new designs.

(*a*). *Operating Performance Over a Range of Service Voltages.* AIEE Standard No. 29 states in part ". . . At the end of any performance at or within its interrupting rating, the circuit breaker shall be in the following mechanical condition . . . the breaker shall be substantially in the same mechanical condition as at the beginning. . . . After a performance at or near its interrupting rating, it is not to be inferred that the breaker can meet its interrupting rating without inspecting and, if necessary, making repairs. . . ." It is no longer considered satisfactory for a circuit breaker to interrupt the circuit and merely not blow up. Modern interrupting devices are generally expected to interrupt their rating without requiring any great amount of maintenance. These operating requirements necessitate the use of durable and simple parts. The arcing contacts in particular should consist of material which will effectively resist the maximum rated interrupting amperes at low-service voltage.

(*b*). *Interrupting Ability at Reduced Service Voltage.* From a practical application standpoint, the interrupting ability of the breaker in amperes at service voltages below the name-plate rating (for example, with a 15-kv breaker, service voltages of 5.0 and 7.5 kv) is vitally important. Some difficulties have been experienced with recent installations of modern 15-kv oil circuit breakers when called upon to interrupt considerably less than their maximum rated amperes (or kilovolt-amperes) at the lower service voltages due to excessive burning of the arcing contacts.

(*c*). *Reclosing Duty Derating Factors.* The theory of operation of air circuit breakers and examination of their component parts would lead one to expect them to be well suited for repetitive reclosing duty cycles, and on this basis it seems doubtful if any derating factors are necessary for such service. In any event, these factors should be materially less severe than with the conventional type of modern oil circuit breakers. We should like to ask the manufacturers as to whether or not tests have been made to determine the performance of air breakers on multiple reclosures and what the effect might be of the number of shots and the time interval between them on the interrupting ability of the breakers and the subsequent maintenance required.

(*d*). *Insulation Levels.* The name-plate voltage rating of a circuit breaker is oftentimes not a correct index of the insulation level for which it was designed. Definite values of insulation levels should be given on circuit-breaker name plates in terms of both low frequency and impulse-withstand test voltages.

(*e*). *Structural Arrangement and Space Requirement.* It is quite likely that as these developments proceed there will be numerous installations of air circuit breakers as replacement of oil circuit breakers and wherever possible the designs of the new air breakers should be such as to permit their installation in conventional-type cells used with oil breakers. This has been given consideration by some of the manufacturers and certain of the designs now on the market can be readily installed in place of oil breakers. Some of the other designs, however, are not so readily adaptable.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper portrays an interesting development of a compressed air breaker in space factors suitable for modern metal-clad switchgear service. This breaker is doubtless adequate for the service intended since the current and voltage ranges involved are well within the limits of the cross-blast principle used. The flexibility of the compressed air type is well demonstrated in this design where the air leaves the tank at the top, passes down through an interrupter, and then reverses to reach the atmospheric vent again at the top of the device.

It seems to me, however, that the use of compressed air for this moderate capacity represents a marginal application since self-contained dry air breakers have been produced which do not require air equipment and this must mitigate against the use of the device in station auxiliaries and other small groupings. It is interesting because of its small size. We had not thought to use compressed air in this low capacity.

The vertical-lift design used originated some years ago for oil breakers which naturally have vertically arranged terminals and where the vertical lift is desirable because of the oil content. It does not appear, however, that vertical lift conveys any definite advantage on dry-type switchgear and it is the writer's opinion that horizontal drawout arrangement is definitely better suited for the newer type of equipment.

In this connection not all customers will accept the metal-clad arrangement and some will desire to arrange breakers in concrete or steel cells and for such purposes a horizontal arrangement of the main electric circuit is frequently desirable.

The accessibility of the design given by the authors may be questioned by operating people. The breaker unit is completely boxed in except for the terminals and even when withdrawn from the metal enclosure very few parts of the breaker are visible for inspection or accessibility for repair. The test data given in tables I and II show the design entirely adequate for its rating, the operating speed from trip impulse to inter-

Figure 1

ruption is fast enough for all commercial use, and the arcing times are short. The debatable points about the design seem to be the use of compressed air for this limited capacity; the general arrangement as it affects station layout; and cell structure design and accessibility of parts as affecting inspection and maintenance.

STATIONARY CONTACT
BLAST VALVE
AIR TANK

Figure 2

Figure 1 of this discussion shows a horizontal drawout self-contained dry breaker for 250,000-kva capacity 15,000 volts and below, which we feel would be favored over a device requiring compressed air.

Figure 2 of this discussion shows an arrangement of compressed air breaker which we feel has advantages as to efficiency and inspection; in it grounded metal parts, including tank valves, and lever mechanism, are all arranged at the bottom, the interrupters are mounted on the tank, and mufflers or other means for discharging used gas are arranged overhead away from operators and high-tension electrical circuits. This seems to us the most desirable arrangement of compressed air apparatus for circuit interruption.

D. C. Prince (General Electric Company, Philadelphia, Pa.): In this very interesting paper, the authors described what are believed to be the first oilless circuit breakers sufficiently small and compact to be competitive with oil circuit breakers in metal-clad gear. The paper also contains valuable new material of a theoretical nature bearing upon the mode of operation of the device. Figure 5 shows clearly the greater importance of the regions where the arc is cut, as compared with those where it is supposed to be most exposed to cooling.

Dr. Slepian in discussing the paper, "The Cross Air-Blast Circuit Breaker," by Prince, Rankin, and Henley, presented at the last winter convention, attributed the operation to cooling along the arc and between the barriers. It is believed that the evidence in figure 5 is fairly clear to the contrary.

It may be questioned why the matter of circuit-breaker theory continues to absorb so much attention in the minds of circuit-breaker designers. The reason is a very practical one. One of the heavy charges incurred in the development of high-power circuit breakers is that due to large-scale testing. The cost of this testing goes up rapidly as the size of the circuit breakers to be tested goes up. Many years ago, the full-power test of steam turbines was discontinued because of the prohibitive cost of both steam generation and power absorption facilities. It is now recognized that because of the very comprehensive knowledge of the behavior of the steam turbine, such full-scale testing is not necessary. The substantiation of the displacement theory of breaker operation places similar knowledge in the hands of designers of such type of circuit breakers as employ this principle, and it is then possible to predict with considerable accuracy the behavior of such circuit breakers, far beyond the capacity of existing testing plants. This represents a very large potential saving to purchasers of switchgear.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): The authors of this paper deserve credit for having given a clear description of the theory and construction details of the air-blast circuit breaker, particularly as applied to metal-clad construction.

It may be of interest that the job here described was installed in the new Central City substation of The Scranton Electric Company in Scranton, Pennsylvania, and that a similar job is being installed in the Third Street substation of The Ohio Power Company at Canton, Ohio.

It may also be of interest to discuss why we are co-operating in this development. Some of the reasons for this are as follows:

1. Almost all of our small or medium-capacity breakers are used in automatic unattended stations, generally indoors. While experience with oil circuit breakers has been quite good, at the same time there is always the possibility of an oil fire in case of a serious breaker failure. One solution for eliminating the bad effects of such a contingency is the installation of CO_2 fire protection but this, of course, is quite expensive. The air-blast breaker eliminates this possibility entirely.

2. In some applications, such as in power station auxiliaries, it is frequently necessary to install breakers in crowded locations where also the temperature conditions may be quite high. Obviously, the elimination of oil in these cases is highly desirable. A specific instance of this sort I previously discussed in connection with the paper presented at the summer convention in 1938 entitled " 'De-ion' Air Circuit Breakers for A-C Feeder, Motor Starting, and Station Auxiliary Service" by R. C. Dickinson, and published in Electrical Engineering under date of November 1938.

3. Inherently, this equipment is lighter in weight than corresponding oil circuit breakers and perhaps ultimately should give us lower-cost switchgear.

While recognizing these actual and possible advantages of the air-blast circuit breaker, at the same time we must not lose sight of the fact that this equipment is radically new in principle and design as compared with the years of background enjoyed by the oil circuit breaker and that many details of design and construction will have to be watched rather closely, at least for some little time. For example, it is certainly true that the breaker in its present design is considerably more complex than the corresponding oil circuit breaker and, if it is found that the breaker has a tendency to get out of adjustment easily, the cost of maintenance may go up. This does not mean that there is any fundamental reason why such difficulties cannot be ironed out eventually, but all of our experience indicates we may expect to go through the inevitable period of childhood diseases before we finally get a satisfactory mechanical job. In this respect I am not only inclined to agree with the authors that one of the outstanding and immediately available advantages of this type of breaker is a sure reduction in maintenance cost, but on the contrary, I am fearful that high maintenance costs may hinder the rapid expansion of application of the breaker.

I feel confident, however, that while such difficulties are to be expected, nevertheless they can and will be overcome and that we have reason to look forward to the time when the complexities of the present design will be appreciably simplified. It is because of this that we are co-operating in the development: We believe that such a course will enable us to more easily gain the material advantages which this breaker should inherently be able to offer.

R. M. Bennett and **B. W. Wyman:** Dr. Slepian's discussion raises interesting questions concerning the mechanism of arc extinction. He asks what we believe to be the translatory velocity of the gas in the region where the arc lies. Tests have been made to determine this gas velocity for use in the displacement formula. These tests were made with a single-barrier arc chute with a transparent side. The speed at which the arc was blasted out by the high-velocity air after it had struck across the opening is clearly shown in the photograph, figure 3 of this discussion. In this photograph the arc forms two loops in the openings of the arc chamber. The left-hand loop had previously been short and portions of it are being rapidly driven down the air passage by the air.

These two photographs were taken $16\frac{2}{3}$ microseconds apart and are representative of a large number of tests. It will be noted that the vertical translatory portion of the arc along the barrier travels at a higher velocity than the middle of the loop as indicated by the points marked on the photograph. The velocity in the middle of the loop is 1,600 feet per second while the vertical translatory portion is traveling at the rate of 2,800 feet per second. The increased velocity in the vertical translatory portion of the arc is undoubtedly due to the evolution of gases from the barrier surface by the intense heat of the arc. These gases evolved by the fiber being chiefly hydrogen have very low density and viscosity and are therefore capable of attaining extremely high speeds. These gases force the arc away from the barrier into a region of high velocity favorable to rapid insertion of a wedge of dielectric.

A wide variety of barrier materials have been tested in the design of air-blast breakers. In general the nongas-forming materials have proved inferior for the construction of arc chutes. Whether or not gas formation is necessary to hold the arc in the region of high velocity, is not proved by these tests for the inferiority of the nongas-forming materials tested can be accounted for by the fact that the surface of the barrier material becomes conducting when subjected to the intense heat of the arc. The extent to which these nongas-forming materials become conducting in the presence of the arc, and the time which they require to regain insulation strength after the arc has been removed have been studied in the laboratory. These insulation-recovery times are much too long for use in air-blast circuit breakers.

Gas evolution from the fiber then performs three functions: first, to provide thermal protection for the insulating surfaces of the arc chute; second, to force the arc away from the barrier into a region of high velocity; and third, to act as a low-viscosity low-density lubricant making possible rapid insertion of a wedge of dielectric at the current zero.

Plotting arc length against interrupting ability yields little information in the case of the air-blast breaker where interrupting ability depends upon the number of breaks in the arc stream. The tests made at reduced air pressure and plotted in figure 5 of the original paper show that interruption of a circuit having a given rate of rise of recovery voltage requires a definite number of breaks in the arc stream regardless of the current magnitude.

The development of the high-voltage air-blast circuit breaker introduced the problem of physical application of the breaker to mounting structures. It was highly desirable to include in the design of this breaker the necessary features to make it suitable for the vertical-lift metal-clad type of switchgear structure in order to retain the advantages already gained through the long use of vertical-lift metal-clad switchgear with oil breakers.

It was early recognized that the contour of the air breaker should conform as closely as possible to that of the oil breaker in order to conserve space in the usual switching structure. It has been possible to retain the vertical lift and easily removable circuit-breaker feature which has been found so useful in the oil-breaker metal-clad switchgear. The advantage is the continuance of a design which has proved its utility in the field. Therefore, no new station designs are necessary nor need any conceptions of this type of equipment be changed. The configuration of the elements of metal-clad switchgear of the vertical-lift type using either oil or oilless breakers is the most economical in floor space and the most convenient in adaptability to the various circuit arrangements where double busses or by-pass disconnecting switches have to be used.

Circuit-breaker configuration is really dictated by the design of an economical and suitable mounting structure for location of control panel, main busses, instrument transformers, and space for cable potheads which can leave interchangeably from below or above. It is much easier to accommodate these features in a structure using vertical-lift breakers. The location of these elements when used with a horizontal draw-out type of breaker is a problem, for if the main bus is connected to the upper studs of the breaker, then there usually is not enough distance between the lower set of studs and the floor to mount one or two sets of current transformers per phase and have enough space left for cable potheads and room for the make-up of cable joints to these potheads. If the busses are connected to the lower studs they come close to the floor and

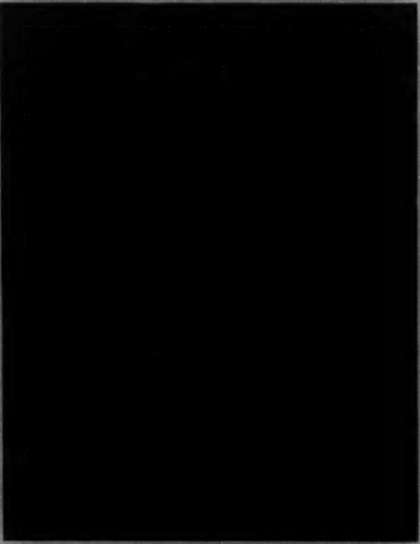


Figure 3

then the problem of cables leaving from below is encountered.

A circuit breaker designed for vertical-lift mounting can be handled by a maintenance man much more easily and quickly because of its decreased weight as compared to one which is mounted in a heavy frame truck.

It is important to have a physical separation of primary disconnecting-device contacts when the breaker is moved from the connected to the test positions. This has been satisfactorily accomplished in the vertical-lift design.

The installation costs are higher with the horizontal drawout type because more care must be taken to insure level station floors and a level entrance surface for each unit. It is extremely fortunate that a type of interrupting unit has been selected that will adapt itself to any breaker configuration, thus allowing the desirable features of the vertical-lift arrangement to be maintained.

Mr. North brings up the question of the application of these breakers at reduced service voltages. The test data at 4.2 kv show the ample margin of safety in this direction. As to reclosing duty derating factors, oil circuit-breaker derating factors are the result of years of field experience combined with laboratory test data obtained by different manufacturers on their various designs of breakers. These derating factors set up for oil breakers are satisfactory for air breakers and are probably conservative as Mr. North points out.

Insulation levels are being worked on by various committees for the co-ordination of insulation levels. As we have always done in oil circuit-breaker design, our insulation level is set up to meet these requirements.

Dielectric Strength of Water in Relation to Use in Circuit Interrupters

Discussion and authors' closure of paper 40-86 by Joseph Slepian, C. L. Denault, and A. P. Strom, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941, pages 389–95.

D. C. Prince (General Electric Company, Philadelphia, Pa.): This very interesting paper seems to substantiate almost the opposite conclusion to that premised by the authors. Although changes in water resistivity would appear to alter the heating of the water by a factor of 200 billion, yet this extraordinary range does not produce any important effects for the short time the voltage is impressed upon the water in circuit-breaker operation. This would appear rather conclusive proof that heating is not an important factor.

Practical experience substantiates this conclusion. Water circuit breakers seem to operate as well on tap water as on perfectly pure distilled water and their operation does not appear to suffer appreciably from contamination of the water in service.

It may be wondered whether conclusions may not legitimately be drawn in another direction from these observations. If the heating of the water has so little effect that a variation of 200 billion is unimportant, perhaps it might be reasoned conversely that cooling of the arc by the water is also an unimportant phenomenon. The authors show that the dielectric strength of the water is a considerable fraction of that of oil, and it is known that this fraction is not changed markedly over a wide range of water resistivity. In the displacement theory, it is the dielectric strength and not the cooling which is important, and the data in this paper would seem to offer evidence that it is the dielectric strength and not the cooling which is the important property in water circuit breakers.

W. F. Skeats (General Electric Company, Philadelphia, Pa.): This paper is an interesting contribution to our knowledge and understanding of the phenomena of nature. The thesis that a long-time breakdown of a water gap is a heating phenomenon seems to be well substantiated.

A study of those tests in which the dielectric stress was high enough to cause breakdown before the boiling point was reached shows that the ratio of water dielectric strength to oil dielectric strength even for these tests is considerably less than the 70 per cent indicated by the surge voltage tests, a strength of 14,000 volts for a one-eighth-inch gap in water corresponding to a value of 40,000 to 50,000 volts for a one-tenth-inch gap in oil. Does this, in the opinion of the authors, represent a reduction in the dielectric strength of water with increase in temperature even before the boiling point is reached?

About a year ago some impulse-breakdown tests were made on tap water with a resistivity of the order of 5,000 ohm-centimeters. The results of these tests are shown on the slide. These show the dielectric strength of this water to be approximately 60 to 65 per cent that of oil as compared with the 70 per cent which the authors have obtained for distilled water of about ten times the resistivity. It thus appears that the dielectric strength of water may be substantially independent of the resistivity.

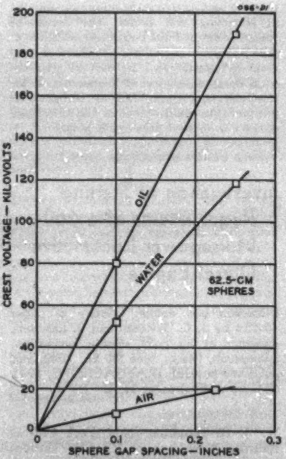

Figure 1. Impulse breakdown strength of insulating oil and tap water

Andrew Gemant (The Detroit Edison Company, Detroit, Mich.): It is known, especially from the work of M. Wien, that water is able to maintain high voltages for a short time, but the present paper seems to be the first investigation on the actual breakdown strength of water. It finally clears away the old distinction between conductors and insulators. Such difference does not exist, at least not for impulse voltages, since the conductivity does not matter in this case. Any material becomes an insulator against surge voltages, if placed between electrodes of a resistivity a few orders lower than that of the material in question, that is, if it is possible at all to apply an impulse voltage to the material. Carrying this idea further, one could say that, if it were possible to construct electrodes of a material having a lower resistivity than that of ordinary metals, for example of a metal in the superconducting state, then the ordinary metal would act as an insulator with a finite and measurable breakdown strength.

J. Slepian, C. L. Denault, and A. P. Strom: We wish to thank Dr. Gemant for his very interesting remarks. As he so well states, there is no absolute distinction between insulators and conductors; electrical breakdown of any material may be said to occur if application of sufficient voltage for sufficient time will cause its conductivity to increase many fold. In the case of water, the arc which forms as the boiling point is reached has a conductivity many times greater than the water from which it is formed.

Concerning the impulse-breakdown strength of water, Mr. Skeats' results are perhaps not too far from our own, namely 60 to 65 per cent of that of oil, compared with our value of 70 per cent. We do not believe that this impulse strength is strongly temperature dependent, although we have no data on this point. We base our belief on the fact that the impulse breakdown is insensitive to conductivity of the water, which is the only property which small temperature changes will alter considerably.

Mr. Skeats refers to our tests with short gaps where high gradients caused breakdown apparently before boiling occurred, at gradients much less than those corresponding to our impulse tests, and asks whether these tests indicate a reduction in the intrinsic dielectric strength of water as the temperature is raised. We believe the answer is in the negative. In some of the tests of this type, voltage was sometimes removed before breakdown occurred. Frequently, under such conditions we observed that the interelectrode space was filled with a cloud of small gas bubbles. We conclude that under high stress the bubbles of dissolved gas set free below the boiling point may cause breakdown.

We are unable to understand Mr. Prince's remark that changes in water resistivity do not produce any important effects for the short time the voltage is impressed upon the water in circuit-breaker operation. Nearly 100 tests are described in our paper which cry out eloquently that the breakdown time for a given voltage varies proportionally with the resistivity for breakdown times ranging from a fraction of a cycle to many cycles.

The Application of Electricity for the Auxiliaries of Railroad Trains

Discussion of paper 40-123 by J. E. Gardner, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 34–6.

W. S. H. Hamilton (New York Central Railroad, New York, N. Y.): Several points are brought out by Mr. Gardner on which I wish to comment.

Mention is made of the use of Diesel and propane gas engines applied to each car for operation of air conditioning and furnishing of other auxiliary power. This opens up some very interesting possibilities and is deserving of careful consideration. As this arrangement is just in the initial development stages it is too early to say just how far it will occupy the field in the future. There are many reasons why a Diesel engine set is highly advantageous for the purpose, the main reasons being continuity of power supply independent of whether the train is in motion or not; the ability to dispense with wayside facilities at outlying points; and the possibility of elimination of large sized storage batteries with their renewal expense.

Against these advantages must be balanced the unknown cost of maintenance of the Diesel engine-generator set required. However, with the developments that are proceeding rapidly in the light weight high-speed Diesel engine field [illegible] believe that the advantages will be found to outweigh the disadvantages and that this method of power supply will become an accepted one on air conditioned cars in the future.

Fluorescent lighting is also mentioned. There is no question but that this type of lighting is most advantageous for car lighting. At present it is necessary on cars equipped with a 32 volt d-c lighting system to use some method of inversion to secure a-c power for operation of the tubes. Several types of means for this inversion are available and probably all will be used more or less in the future. While there does not seem to be any possibility at the present time of securing a fluorescent tube that will operate directly on 32 volts direct current, I am confident that one will be developed in the next few years and that the problem while difficult is not insurmountable.

Those railroads which with the advent of electro-mechanical air conditioning adopted 64 volts direct current, now have an additional reason for congratulating themselves on their choice. Fluorescent lamps are now available for use directly on 64 volts d-c supply. These lamps are 15 inches in length, instead of 18 inches as used commonly for lamps operating on alternating current. Stroboscopic effect is of course eliminated and the auxiliaries are very simple consisting of a magnetic switch and a small ballast lamp. They are rather sensitive to voltage variations however and require the use of a lamp regulator but the size necessary for the same illumination is considerably reduced since a fluorescent lamp taking approximately 22 watts total input gives about the same light as a 40 watt incandescent lamp. The efficiency including losses in the lamp regulator is about the same as lamps operated from alternating current through inversion equipment, but the simplicity and ease of control is greater.

The New York Central has had one coach number 2562, with these lamps in operation since October 1939 with entire success and three additional cars are being equipped at the present time.

On cars having 32 volt d-c lighting it is possible also to use a small d-c booster set and secure 64 or higher d-c voltages for fluorescent tube operation. Such an arrangement has the advantage that stroboscopic effect is eliminated and by making the output voltage about 75, standard 18 inch a-c tubes may be used.

It is to be hoped that there also will be developed in the future fluorescent lamps of a more concentrated type that might be used in fixtures such as on platforms and in passageways where the long tubular type of lamp is not so desirable. Such lamps of the cold cathode type have been made but require high a-c voltages for their operation. No doubt the time will come when they will be available for operation on lower a-c voltages and perhaps directly on direct current.

In closing I wish to point out that if the full benefit of fluorescent tubes is to be secured, the fixtures in which they are used must be such as to use the minimum amount of screening and permit the maximum transmission of light consistent with a reasonably good appearance. There is too great a tendency on the part of architectural designers to use arrangements of fixtures that absorb too much of the light output and thus nullify much of the advantage of the use of these fluorescent lamps.

Investigation of Starting Requirements of a 660-Horsepower Locomotive Diesel Engine

Discussion and authors' closure of paper 40-124 by J. C. Davidson and R. Lamborn, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 31–4.

W. S. H. Hamilton (New York Central Railroad, New York, N. Y.): The authors are to be congratulated on having set forth clearly and concisely many of the problems and phenomena that take place in the starting of a Diesel engine and for pointing out facts which have not been clearly understood in the past.

It is to be hoped that this paper will stimulate other manufacturers to present similar papers on other engines so that a more thorough study of the whole problem may be made.

Data such as this is very important in determining the number of cells required in the starting battery. Recently there has been a tendency to standardize on 32 cells of lead-acid battery for the larger sizes of engines, say 300–1,000 horsepower, and 16 cells for the smaller ones. These follow the accepted standards in the car lighting field and it will be interesting to see how large an engine it will be found possible to start from a 32 cell lead-acid battery. From the user's standpoint the fewer the cells of battery, the better on account of maintenance.

With the smaller Diesel engines, starting motors are frequently used and in connection with them I believe some erroneous impressions have arisen probably carried over from experience with gasoline engines. Gasoline engines require a spark for ignition which naturally cannot be secured if the battery voltage is allowed to go too low during cranking. The usual limit is about 1.0 volt per cell, I believe. Due to this requirement apparently, the tendency has been to select starting batteries with relatively few cells and a large number of plates per cell. While such a battery gives ample breakaway torque, the cranking speed is limited after the engine turns over and there is a tendency for the time required to fire to be lengthened out.

A Diesel engine on the other hand (except those of the Hesselman type) requires no ignition and the battery voltage can be allowed to go much lower, 0.5 volt per cell being the usual limit. Of course sufficient current to provide breakaway torque must be provided, but on the other hand it is desirable to bring the Diesel engine quickly up to as high a cranking speed as possible in order to heat the combustion air and cause ignition promptly. The combination of these requirements points to the use of a starting battery having "steep" voltage characteristics, i.e., one whose voltage increases rapidly once the engine has started to turn over. This battery characteristic would be obtained by a larger number of cells with fewer plates per cell as compared to the battery that might be selected for starting a gasoline engine. Shortening the time between starting and commencement of firing means that less total kilowatt hours will be required from the battery per start.

This characteristic has been fully recognized in the case of the larger size engines and is shown by this paper, but I do not think it has been fully appreciated by those concerned with the smaller Diesel engines, especially those using starting motors.

I wish to add a word also on the problems of cold engine starting. The relatively large engines used on locomotives do not cool down as rapidly nor are they in general exposed to the outside air as much as are engines in automobiles. Hence it is questionable whether even in severe winter weather the crankcase oil gets anywhere near as stiff as is commonly supposed. We have found by tests on a 300 horsepower engine that the oil hardly gets down to 40 degrees Fahrenheit even in ten degrees Fahrenheit outside air overnight and with doors and windows opened and crankcase covers removed. This feature should be kept in mind in connection with the starting problem particularly in connection with the larger sized engines.

D. P. Orcutt (The Electric Storage Battery Company, New York, N. Y.): This paper is very interesting to me as it gives definite information about the starting characteristics of an engine that I have followed in service from the starting battery side for approximately ten years.

The excellent service record of the electrical cranking equipment used on these engines has been a marvel to me when I consider how little was known of the actual requirements at the time the equipment was designed. It is possible now to consider some of the factors of safety that were in the original design and how they have contributed to this service record.

Test 6 showing how the maximum torque required to start may increase in a hot engine indicates that if initial battery voltage instead of the more conservative value of average battery voltage had been used in the original design, there would have been many failures in service that, with the limited knowledge of the starting characteristics of the engine that were available, would have been hard to explain.

Tests 5 and 9 are especially interesting as representing about the minimum battery voltage that will start the engine. The margin between the voltages in these tests and tests one and seven where the full number of cells were in circuit is considerable, but this margin is no greater than is needed to meet the condition of a hot engine as shown in test 6.

One might gain the impression from comparing tests 7 and 9 that a considerable saving in battery cost might be made by reducing the number of cells from 56 to 40 since the slower cranking in test 9 uses about the same amperes at a lower voltage and therefore less watts. However, test 6 shows that had this been attempted, the engine could not have been started when hot. It would also be true that it could not have been started when the battery was excessively cold due to battery voltage being less under this condition.

There is also a third reason a 40 cell battery of the size used would not be sound engineering. If the watt hours required to make the engine fire in the two tests are calculated, it will be seen that in spite of the fact that the watt input is less with 40 cells, the watt hours are actually about 30 per cent more due to the longer time required to make the engine fire. If the 40 cell battery were engineered with the same factor of safety in number of starts that could be made from the battery, its ampere-hour capacity should be increased so as to make its watt hour capacity approximately 30 per cent greater than that of the 56 cell battery. This, of course, is on the assumption that the same generator windings are used with both batteries.

The tests presented so carefully in this paper confirm my belief that the most satisfactory and the most economical cranking of Diesel engines is obtained by a design which provides rapid acceleration and high speed in cranking. This is even more important under cold conditions when radiation losses are greater or when wear increases the "blowby" of the pistons.

Some of us who have had to live with the results of the early engineering applied to starting of Diesel electric locomotives have been and are deeply grateful for the "leeway provided by the manufacturers" as referred to by the authors under the heading "Conclusions."

R. Lamborn: The discussions by Messrs. Orcutt and Hamilton emphasize the value of definite testing information in connection with selecting starting equipment for Diesel-electric locomotives. Mr. Orcutt has pointed out the necessity for adequate battery equipment whether starting cold or hot. In this connection it should be pointed out that the results shown by the authors apply to a certain specific engine, and as Mr. Hamilton has brought out in his discussion additional information on other engines should be obtained for the benefit of equipment designers and locomotive builders.

An Improved Type of D-C Wattmeter of the Shunted Type

Discussion and author's closure of paper 40-88 by Paul MacGahan, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940 and published in AIEE TRANSACTIONS, 1941 (January section) pages 4–7.

Perry A. Borden: See discussion page 634.

H. N. Walker (New York University, New York, N. Y.): It is remarkable that after 50 years of progress in instrument design, we are still using ammeters and voltmeters for measuring d-c power, thus involving the necessity of two independent readings and a multiplication. Admittedly on most d-c circuits the voltage is reasonably constant, so that current as indicated by switchboard ammeters is usually a satisfactory guide of load.

The great advantage of the so-called d'Arsonval shunted ammeter, and the inconvenience of electrodynamic wattmeters which could not be operated with equal accuracy from ordinary ammeter shunts, has tended to suppress advancement along the lines followed by the author. A reading of d-c power is often preferred over separate readings of amperes and volts, particularly with the varying voltages.

There is nothing new in any of the components of the d-c wattmeter as developed by Mr. MacGahan. However, the resultant assembly itself is new. This paper is an interesting example of how an entirely new and useful device can be produced from existing components. Mr. MacGahan's wattmeter is evidently a hybrid of the d'Arsonval structure and the electrodynamic principle of operation. Operation from a shunt is made possible by retaining the low energy input level of the permanent-magnet instrument. The use of Hipernik for the core material of the electromagnet minimizes residual errors. I believe that a contribution to the art of instrumentation has been made in that, and so far as I know, these things have never been done satisfactorily before.

It is interesting to me to note that progress in the art of instrumentation does not necessarily involve the discovery of new principles, so much as it does the exercise of skill in combining known principles and existing facilities so as to meet a demand.

The question of contact resistance which Mr. MacGahan touches upon is one which seems to me to be too little appreciated by most electrical engineers. It may be interesting to point out that the contact resistance of even copper to copper can be appreciable and prolonged. It has been observed that such contact resistance steadily decreases over periods as long as two months and more. I should like to point out that, up to this time, there has been no adequate explanation given for this phenomenon.

Paul MacGahan: As pointed out by Mr. Borden this instrument was only made possible by the development of new materials. This condition is true in all new developments. Thus the steam engine had to wait many years for the advent of steel before it could be built and thereby bring on the industrial age. As exemplified by Mr. Miller's wattmeter no "principle of operation" can ever become "obsolete." It can only become temporarily set aside until new conditions, or new materials bring it forward again to new uses.

One of the remarks made during the discussion was that such instruments have been made before. It sometimes seems to me that everything new has been made before. Erikson discovered America before Columbus. Many steamboats were sailing ahead of Fulton. Edison discovered the Edison effect in the vacuum of a lamp bulb, Hertzian waves were known and studied, and the spoken word was carried on the wave before Conrad—whose broadcasting achieved revolutionary changes in human affairs. So let us agree that achievement is not invention—but consists rather in "putting it across" at the proper time.

Development in instruments as in other fields has reached a new phase. No one achievement can stand out in advance of the general front of progress. Progress on any section must necessarily depend upon that of other sections.

A New High-Speed Thermal Wattmeter

Discussion and author's closure of paper 40-97 by John H. Miller, presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 37–40.

P. M. Lincoln (Therm-Electric Meters Company, Inc., Ithaca, N. Y.): John H. Miller's paper describing "A New High-Speed

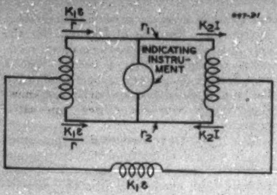

Figure 1

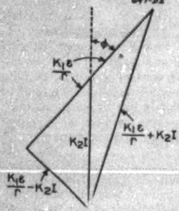

Figure 2

Thermal Wattmeter" is an exceedingly interesting one. It describes a method of measuring watts with which I have been experimenting for over 30 years. It is a method of measuring, which in my opinion, is sure to see much more use as time goes on.

Mr. Miller has described a very ingenious method of securing rapid response. My own experiments have been directed toward physical construction of such a nature that the response would be inherently slow so that the device could be used for the measurement of "maximum demand."

Let us carry Mr. Miller's analysis a little further. Figure 1 of this discussion is based on Mr. Miller's figure 2. Let us assume that the resistance of the hotter of the two rows of thermocouples is r_1 and of the colder is r_2. If $r_1=r_2$, it is obvious that the current through them due to the voltage of the circuit under measurement is $2K_1E/r$, where K_1 is the ratio of the potential transformer and r is the resistance of each of the two rows of thermocouples.

The current of the circuit under measurement is caused to superpose upon the potential current in the manner shown in Mr. Miller's figure 2. The value of this current is obviously K_2I where K_2 is the ratio of the current transformers. The total current in r_1 thus becomes $K_1E/r+K_2I$ and that in r_2 becomes $K_1E/r-K_2I$. The heat generated in resistances r_1 and r_2 is, of course, proportional to the squares of the currents therein. Therefore, the heat generated in resistance r_1 is $(K_1E/r+K_2I)^2r_1$ and that in resistance r_2 is $(K_1E/r-K_2I)^2r_2$. Mr. Miller's setup is such that his measuring instrument gives the difference between these two values of heat. This obviously reduces to $4K_1K_2EI$.

However, the above analysis takes no cognizance of power factor. If the power factor is other than unity, the currents in our resistances due to potential and to the current itself are no longer directly additive and subtractive. The phase angle between the two must be taken into consideration. This is done in figure 2 of this discussion. From trigonometry it is obvious that the current values in resistances r_1 and r_2 are those given in figure 2. Taking power factor into consideration, it is obvious that the voltage applied to Mr. Miller's measuring instrument is $4K_1K_2EI \cos \phi$.

However, it should be borne in mind that the integrity of the above analysis is based on the assumption that $r_1=r_2=r$. If Mr. Miller's rows of thermocouples are composed of materials of zero temperature coefficient, the above analysis will hold true. If, however, there is an appreciable temperature coefficient in the thermocouples, the currents therein due to the voltage E no longer divide equally between the two rows of couples and there will be an error of measurement. This is particularly true on low power factors where the currents flowing through the thermocouples are much increased. It would be of interest if Mr. Miller would give us some information on the temperature coefficient of his thermocouples.

G. S. Lunge (General Electric Company, Schenectady, N. Y.): This new high-speed thermal converter, more familiarly known as the "thermoverter," is especially welcome in the field of carrier telemetering.

With it, it is now possible to totalize economically a number of readings at the transmitting end of the telemeter channel, and even to add in additional readings at intermediate points along the route, all without appreciably impairing the over-all speed of response of the impulse-telemeter equipment. Only impulse telemeters have found general application to carrier channels, because of the simplicity and closer spacing possible of channels so used. Until the advent of the thermoverter, the excessive time lag inherent in thermal converters nullified the reasonably rapid response of the impulse-telemeter equipment and usually necessitated recourse to other methods of totalizing.

Now the sum of the thermoverter-output electromotive forces can be measured immediately (rather than only at regular intervals) by a self-balancing potentiometer, the slide-wire rheostat-arm position of which is "scanned" by an impulse-duration telemeter ("metameter") cam, thereby converting the d-c electromotive force into on-off carrier keying impulses as a single operation, with minimum delay.

The same type of potentiometer device can be used to advantage when a carrier telemeter reading is to be retransmitted to its final destination after adding to it one or more readings that can be obtained by means of thermoverters located at or near the retransmission point. The carrier telemeter receiver at the retransmission point in this case is arranged to provide a suitable (and preferably ripple-free) electromotive force proportional to the quantity measured, for addition in series with the thermoverter electromotive force.

Care must be taken not to destroy the advantage of the rapid response of the thermoverter to changes in load by inappropriate choice of the carrier telemeter system used to transmit the reading or retransmit the totalized value. The impulse-duration telemeter (metameter) is particularly well suited to take full advantage of the high speed of the thermoverter, as, different from the impulse-frequency telemeter, the metameter does not require the thermoverter electromotive force to be converted (by necessarily indirect means) into proportional mechanical rotational speed before carrier keying impulses can be initiated. The impulse-frequency telemeter can, of course, only transmit readings of such quantities as can be arranged to produce continuous mechanical rotation.

Perry A. Borden (The Bristol Company, Waterbury, Conn.): Though it might not so appear on the surface, there exists between the papers of Mr. MacGahan and Mr. Miller a kinship which makes it desirable that they be discussed simultaneously. Both the d-c wattmeter announced by Mr. MacGahan, and the thermal wattmeter described by Mr. Miller, point to the outstanding advances in the art of measurement, as well as in all other fields of electrical activity, which are made possible by use of the new magnetic alloys. In these cases two quite different characteristics of substantially the same material have been advantageously utilized.

The industry has long demanded a d-c wattmeter which could be operated from a conventional shunt with degree of simplicity and efficiency to compare with that of the d-c ammeter; and the instrument described by Mr. MacGahan appears to fill the need.

The rapid response and relatively great power output characterizing the thermal wattmeter described by Mr. Miller have vastly broadened the field of measurement to which this principle may be applied. The fact that it may be used with a rugged millivoltmeter type of indicating instrument over a considerable length of line greatly simplifies power measurement, especially where totalizing is involved, even though the distance is not sufficient to justify application of the term "telemetering". When used with a self-balancing potentiometer, the practical speed of response is limited only by that of the recording instrument, and its performance is eminently suited to automatic load control. The low internal resistance of the output circuit greatly increases the flexibility of use, and makes possible the simultaneous determination of subtotals and a grand total where several groups of feeders are involved.

Now, with the advent of the instrument described by Mr. MacGahan it becomes equally easy to obtain a measurement of d-c power in a form suited to telemetering and totalization, thus providing a practical solution to the long-standing problem of totalizing a-c and d-c power loads on a common instrument.

John H. Miller: Mr. Lincoln asks for the temperature coefficient of the thermocouples. The mean temperature coefficient of the two materials used is 0.00117. However the change in resistance in r_1 and r_2 referred to in the discussion by Mr. Lincoln does not completely determine the distribution of the current obtained from the potential transformer. Since this current flows through several turns in opposite directions on the current transformer, if it tends to separate in other than equal amounts, a differential reactance of a rather high value appears which forces the even distribution of this current in the two parallel circuits.

Actual tests show that if one resistance increases as much as ten per cent above the other, feeding these currents through the split winding on the current transformers will result in less than one per cent difference in the two current values.

The values of r again come in as a function of the generated heat, but if they increase as a function of the temperature, they simply increase the slope of each curve and do not change the form so that such differences can be calibrated into the device through a single spot calibration by means of the adjustment of resistance in the primary of the potential transformer.

Thus we see that actual resistance variations in the thermocouples give rise only to second-order errors and as a practical matter the output curves are quite straight and the compensation for the temperature coefficient of resistance is inherent at least as to first-degree errors.

The Vertical-Flow Interrupter and Its Application to "Oil-Poor" Circuit Breakers

Discussion and author's closure of paper 40-114 by B. P. Baker, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941, pages 440–5.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The development outlined by Mr. Baker was initiated in this country to protect the switchgear industry in case the high-voltage oil-poor interrupters used in Europe should demonstrate adequacy for our conditions. The improvements made in dead tank breakers have so far proved satisfactory to operating people and there has been no insistent demand for the oil-poor device. On the other hand the improvement in circuit rupture made possible by this development has been of decided interest in certain European countries and this design is in extensive manufacture in Italy and it is being taken up in a preliminary way in England and Japan.

The results given in the paper, both on factory and field tests, show that interruption occurs in the minimum of time and with great arc efficiency. This makes possible the handling of heavy powers in the limited space and strength of structure provided by a porcelain enclosure.

For use out of doors the device is admirable, in that there is no exposed disconnect switch or operating linkage. The remote control rod passes through the current-transformer chamber, is immersed in oil at all times, and its sole action provides the interrupting break and the disconnect function as well.

Both the interrupting chamber and the transformer chamber are lined with Micarta tubes which preserve the assembly of the breaker in case of porcelain failure so that the porcelain serves only as a weather shield.

The paper describes in detail a 138-kv size but the same structure with dimensional modifications is good for 115 kv and 161 kv. In Italy at the present time a similar structure using two columns is in production for 230 kv.

The Southern California Edison Company is to be commended for its interest in this new development, and for the valuable tests made on it at the Laguna Bell station. While the particular unit tested in the field was designed for 138 kv it handled efficiently short circuits to ground on the Southern California 220-kv system up to approximately 2,250,000 kva on a 3-phase basis.

The transportation of this porcelain structure across the country by railroad and back again, and its erection in California without incident is reassuring to those who may question the adequacy of such a structure for practical switchgear requirements.

J. D. Laughlin (Bureau of Power and Light, City of Los Angeles, Calif.): The paper presented by Mr. Baker emphasizes two important phases in the present trend in the development of high-voltage circuit breakers, namely the reduction of oil requirements and the reduction in interrupting time. Development along these two lines should be very welcome to purchasers of this type of equipment.

The radical departure of this circuit breaker from the conventional oil circuit-breaker design illustrates a phase of the work being done to produce circuit breakers that will not require the large quantities of oil used in past designs. The reduction in oil requirements from past circuit-breaker design should prove of great benefit in the reduced costs of handling oil during construction and in the reduced requirements for oil maintenance and reduction of fire hazard during operation of the equipment.

The data from the tests made on this breaker indicate that it will interrupt currents in times comparable with the fastest conventional type circuit breakers and its interrupting time is approximately constant throughout its capacity range. This fast interrupting time should prove valuable in increasing the transient stability of systems with long transmission lines.

In the construction of the Boulder transmission system, the Bureau of Power and Light of the City of Los Angeles has taken advantage of the use of high-speed low oil content breakers. By using circuit breakers with three-cycle interrupting time, the transient stability of this system was increased over what could be obtained using breakers of conventional design. At each of the two intermediate switching stations, six low oil content 287,500-volt oil circuit breakers are installed. The total oil requirement for the six breakers at each station is 14,000 gallons as compared with a requirement of 140,000 gallons for conventional tank-type breakers of equivalent rating. The greatest quantity of oil in any one compartment in the breakers used is 150 gallons as compared with approximately 8,000 gallons in the tank-type breaker. Due to the low oil requirements of these breakers, no oil handling equipment is installed at these stations. All oil at these stations is filtered and handled with a portable outfit consisting of a filter press and tank mounted on a truck. This piece of equipment is normally used for maintaining equipment at other scattered installations. If tank-type breakers had been used at these stations, it would have been necessary to install special oil storage tanks and oil handling equipment at each station.

In the design of the circuit breaker described in this paper, porcelain and fibrous insulating tubes have been used to provide insulation between live parts and ground, and also to support the interrupting element function performed by the oil and steel tank in conventional design. These departures from conventional designs introduce new problems that will require research and investigation to develop these parts to a point where they will withstand the combined electrical and mechanical stresses due to repeated operations as well as is being done by the conventional design. I would like to ask what assurance the author has of the structural reliability of this breaker.

The Southern California Edison Company should be commended for making the series of circuit-breaker tests on their 220,000-volt system of which this paper reports one test. Such tests which more closely duplicate service conditions than laboratory tests provide a definite check of the ability of circuit breakers to perform under actual system conditions and furnish both manufacturers and operating companies with valuable information regarding circuit-breaker operations.

H. E. Strang (General Electric Company, Philadelphia, Pa.): Mr. Baker has described an oil-poor circuit breaker, which on the strength of the very satisfactory field tests, merits consideration and study even at this time when the trend of new developments in the industry seems to be away from oil breakers, including the low volume variety, toward the oilless types.

Unfortunately it may be confusing to the engineer who is attempting to correlate practical applications and physical construction of interrupting devices, having various theories of operation, to learn that Mr. Baker states that interrupters used in dead tank breakers are not adaptable to use in porcelain structures.

The original high-voltage low oil content breakers in the United States were placed in service on the 287-kv Boulder Dam line, and on the 138-kv receiving station end in 1936. Requirements for the third line in 1939 placed similar breakers at the Boulder end as well as duplicates of both other locations. These breakers are of the impulse type[1] in which a mechanically operated piston forces a stream of oil *across* the arc paths between each of a series of breaks. This type of operation results in minimum arcing time, since oil pressure is always available at the instant the contacts separate. Application of this same type of interrupter has been made to tank-type breakers for 115 kv to 230 kv[2] in which the flow of oil *across* contacts in series is produced by the gas created by other pressure-generating breaks, instead of a spring-actuated piston. This construction results in slightly longer arcing times, but still short enough to demonstrate over-all breaker operating times of 1.96 to 4.22 cycles on 230-kv field tests on the Southern California Edison Company system in 1937.

The device described by Mr. Baker in which oil moves longitudinally with the arc, appears to be related to the well-known explosion chamber, in which the throat provided the "small hole or chimney in the oil." After having served the industry well for more than a quarter of a century, this type of interrupter was superseded in 1930 by the oil-blast explosion chamber[3] following laboratory and field tests which proved that the cross-blast action was about twice as effective as the longitudinal blast.

Mr. Baker also mentions a flow of oil created by the different displacement of two volumes attached to the moving contact assembly, but neglected to make clear whether this differential volume was of sufficient magnitude to have an appreciable influence. If a relatively large volume is displaced and forced along the arc, the piston of course must be actuated by relatively heavy springs to assure a continuance of the flow against the gas pressure created by the arc, and to avoid contact reversal at such a critical time.

R. A. Hentz (Philadelphia Electric Company, Philadelphia, Pa.): The breaker described by Mr. Baker is a desirable contribution to the high-voltage circuit-breaker art on two scores.

First, it constitutes one more step toward the reduction of the oil fire hazard. The article states that the interrupting compartment contains 60 gallons and, assuming (from figure 4) that the current-transformer compartment contains about twice that amount, we have approximately 200 gallons of oil per single-pole 138-kv breaker. A corresponding dead tank breaker contains about 1,250 gallons. While 200 gallons of oil (600 for 3 poles) can cause a bad fire, the relative hazard as compared to the dead tank breaker means that this new breaker is much to be desired over the old, especially when conditions require a circuit breaker to be installed in a location where fires would have serious consequences. However, the desirability of eliminating all oil from circuit breakers of all voltages still remains the goal toward which the industry should strive.

Second, it seems that this design should result in a marked reduction in first cost, as well as operating expenses. Figure 3 vividly brings out great differences in physical dimensions which should not only make the breaker itself much cheaper, but the cost of such items as handling, foundations, permanent oil piping (probably not needed at all in the case of the oil-poor breaker). It would be interesting to learn from Mr. Baker if there is a reduction in control current, an important item along with permanent oil piping in the case of a widespread substation designed with substantial separation between its component parts.

The breaker appears to have been designed for ready dismantling for inspection which with the smaller quantity of oil is of interest to the maintenance forces.

In testing circuit breakers it is desirable, of course, to perform as large a number of tests throughout a wide range of short-circuit currents as is possible, for the greater the number of tests, the more reliance can be placed on the breaker. But laboratory limitations usually mean that the higher kilovolt-amperes cannot be imposed upon the breakers and operating limitations mean that only a limited number of tests can be made on a utility's system. By subjecting a circuit breaker to both factory and system tests, a satisfactory over-all testing program can often be obtained. This appears to have been the case in the test described in the paper, about 115 factory tests (figures 7 and 8) being made at the factory with an upper limit of about 3,000 amperes at 132 kv and 4,300 amperes at 88 kv and 4 tests at the Laguna Bell substation at higher short-circuit currents (as high as 5,900 amperes at 124 kv).

H. P. St. Clair (American Gas and Electric Service Corporation, New York, N. Y.): Regardless of the ultimate validity of the author's theory as to the actual mechanics of arc interruption, it appears that the breaker described does produce an effective relative motion of oil and arc which results in consistent interrupting performance, at least throughout the range of recovery voltage conditions applying to the tests reported in the paper.

The voltage recovery characteristics obtained on the Laguna Bell tests have been indicated by the author but no data are given for the laboratory tests. As to be expected from the nature of the system connections supplying the fault at Laguna Bell, these characteristics were distinctly low in severity, particularly on the maximum short-circuit values. Presumably, laboratory tests were made at greater severity. It would be interesting to know what these conditions were. It would also be interesting to check the field performance of this breaker on circuits with higher natural frequencies and correspondingly greater rates of rise of recovery voltage.

The mechanical design of the breaker appears to include a number of good points such as (1) the built-in disconnecting contact with full interior creepage distance, and (2) internal support and operating stresses carried by micarta-tube housing, independent of porcelain shells. On the other hand, possible sources of difficulty in this design might include the stuffing gland where the torsion operating shaft goes through the base compartment of the breaker, this compartment as shown in figure 4 being subjected to the full head of oil equal to almost the full height of the breaker. This head appears to be somewhere on the order of ten feet. While this might not create a serious problem, it certainly would necessitate a completely oil-tight construction and the maintenance of an oil-tight stuffing box operating under considerable pressure.

Current transformers continue to present a problem in breakers of this general type and the solution here, while it is a solution, certainly is far from ideal. Access to the current transformers would appear to require complete dismantling of the breaker.

On the whole this breaker represents an interesting development and Mr. Baker is to be congratulated, both upon the developmental work accomplished and the clear and concise description which has been given in this paper.

Incidentally, the industry is indebted to the Southern California Edison Company for another contribution to the art in lending the facilities of their system for high-power short-circuit tests. We in the American Gas and Electric Company system know that to subject a high-voltage system to repeated full capacity short circuits takes a certain amount of courage and a high degree of confidence in the protective equipment on the system. It has always been our conviction, however, that, since such protective devices have been designed and applied to take care of system faults, there is no better time to find out whether or not they are capable of doing so than under staged short-circuit tests where every opportunity is available for careful observance of system performance and weaknesses. Furthermore, we can truthfully say that, in all of our indulgence in short-circuit testing, the benefits from establishing greater confidence in the reliability of our system protective features and in weeding out such weaknesses or deficiencies as have been occasionally disclosed thereby have far outweighed any harmful results in the way of damage to equipment or disturbance to customers resulting from such tests. It is our understanding that the same conclusion has been reached by the Southern California Edison Company in connection with their testing experience, and we are confident that power systems, in general, would reach the same conclusions after going into more field testing. It is our belief, also, that, while the bulk of the research and developmental testing in the design of circuit breakers must necessarily be made in the manufacturers' testing laboratories, at the same time, as a final proof of a design, a full capacity field test is practically indispensable; and that power companies, in general, would contribute to the development of the art and ultimately to an over-all saving in cost by allowing a greater use of their systems for such tests.

A. C. Schwager (Pacific Electric Manufacturing Corporation, San Francisco, Calif.): In 1938 I had the opportunity to visit a large number of circuit-breaker manufacturers and breaker installations in Europe. At that time the grounded-tank circuit breaker had been replaced mainly by oil-poor circuit breakers. These breakers proved satisfactory for the relatively small interrupting capacities encountered there. Mr. Baker deserves credit for having shown that with proper modifications the oil-poor breaker has possibilities for voltages and interrupting capacities as met in this country. In some European designs most closely approximating Mr. Baker's development, oil is pressed vertically through the interrupting chamber. This oil-blast action was found necessary in order to obtain interruption at low currents; without it failure would occur. It would be interesting to know if Mr. Baker's tests confirm these findings.

Today, breakers are more and more called upon for fast reclosing duty and I believe that considerable hazard would be invited in placing such breakers into service without verification of the interrupting ability during such operation. Mr. Baker's test results seem to show that this breaker loses some of its effectiveness under conditions as they must exist during two successive opening operations. In table X, the arcing time for 60 shots is consistently longer than for 0 shots. This might be due to the fact that a vacuum is produced within the chamber during the closing stroke which will annul some of the desired oil-blast action in the subsequent opening operation. When two or more interruptions take place within a short interval, a similar, except more serious phenomenon is likely to occur. After the first interruption, the arcing chamber is filled with gases at considerable pressure and it is difficult to imagine that upon immediate reclosure any amount of oil can be accumulated and be made useful for the second opening. It is more likely that due to the gas pressure additional oil will be expelled from the chamber during the closing stroke. Has Mr. Baker additional test data to clear up this point?

L. B. Chubbuck (Canadian Westinghouse Company, Hamilton, Canada): While porcelain outdoor oil-poor breakers originated in Europe, it is interesting to note the outstanding improvements provided in Mr. Baker's design. Simple efficient interrupting grids are used, also a compression assembly of all porcelain, with no cemented or clamping rings. No cumbersome external air-isolating switch is required, as a simple oil-disconnecting gap is provided directly in the interrupting compartment. This latter arrangement is particularly suitable for high-speed reclosure.

The extended tests carried out in a well-known high power laboratory, and the very successful field tests in California, give confidence in what is, to most American engineers, a new type of breaker.

Where the current transformer can be taken care of separately, the large porcelain current-transformer assembly can be omitted from the breaker. The interrupting chamber can be mounted on three standard post insulators, and the operating rod from the oil-disconnect gap carried down in oil in a skirted porcelain tube to operating mechanism in the base. Particularly for the higher voltages this would provide a very simple and economical design.

R. C. Van Sickle (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The interrupter described by Mr. Baker is remarkable for the relatively small amount of electrical energy which it dissipates as energy of the arc. The amount of this energy is significant as it controls the depreciation of the oil and the pressures within the structure.

The improvements in interrupting devices made about 10 or 12 years ago were sufficient to permit reductions in oil volumes, and breakers in porcelain using small quantities of oil for interrupting purposes and air gaps for insulation appeared in Europe. The smaller oil volumes naturally increased the importance of the features which control the amount of arc energy liberated, namely, arc voltage, arcing time, and current.

The vertical-flow interrupter liberates very little arc energy. This can be seen from the oscillograms used as illustrations in Mr. Baker's paper. In figure 12, he shows three cathode-ray oscillograms and indicates by arrows the arc voltage. Actually these were so low that they are not distinguishable from the zero line. In the original oscillograms which are 18 inches long, they amount to little more than a thickening of the zero line immediately before interruption. The magnetic oscillograms shown in figure 11 do not have the voltage traces superimposed and here too the arc voltage is not discernible. In figure 6 which contains high power laboratory tests to a larger scale, the arc voltage can be seen but is extremely low.

These low arc voltages and the short arcing times produce very little arc energy. This is an outstanding characteristic of the vertical-flow interrupter and makes it particularly suitable for use in high-voltage breakers employing small quantities of oil and enclosed in porcelain.

H. A. Lott (Southern California Edison Company, Ltd., Los Angeles, Calif.): In October 1936 the first of a series of field short-circuit tests at 220 kv were made on an oil circuit breaker at Saugus substation of the Southern California Edison Company. Since that time 136 test short circuits have been made on 11 different types of interrupters. Each short circuit was single conductor to ground, the intensity varying from $^{1}/_{4}$ million to $2^{1}/_{4}$ million equivalent three-phase kilovolt-amperes.

As a supplement to the short-circuit tests, 47 tests were made wherein the three-phase charging current of 220-kv transmission lines varying in length from 22 miles to 246 miles was ruptured by the switch under test.

In each series of tests an oscillogram similar to the one reproduced in figure 11 of the paper under discussion was obtained for each individual short circuit or line drop test. The oscillograms together with tabulations of results and photographs were obtained and are used by Edison engineers as a basis for their recommendations for modernization of 220-kv oil circuit breakers.

The Edison 220-kv transmission system consists of 1,085 circuit miles of 220-kv line which interconnects the three principal sources of generation with the load. Two sources of generation, Boulder and Big Creek are approximately 250 miles from the load center while the third source, Long Beach steam generating station, is about 25 miles from the load center. On such a system where large blocks of generation are remote from the load, high-speed clearance of short circuits is imperative in order to prevent instability following the clearing of multiphase faults.

Because of the necessity for high-speed modern interrupters, Edison engineers are keenly interested in new developments in the circuit-breaker art, particularly when such developments give promise of being useful in modernizing existing breakers. Accordingly the Edison company was willing to extend the use of its system on the several occasions when it appeared desirable to test the performance of newly developed interrupters which might be used on the Southern California Edison system.

The amount of preliminary work and planning necessary to stage a short-circuit switch test is almost inconceivable to one who has not participated in such a program. Edison engineers have developed special relays for starting the oscillograph and closing test switches, they have developed a travel recorder which records the motion of switch contacts and thus indicates the position of switch contacts at any time during the opening or closing stroke of the switch under test, in addition to several other devices which facilitate making the tests.

When short-circuit tests are made at Laguna Bell substation five values of current are used. These values are obtained by switching of lines and busses at adjacent stations in order to place the test breaker at Laguna Bell at the terminal of transmission lines of various lengths which interposes sufficient reactance to give short-circuit currents varying from 600 to 6,000 amperes. The highest value of 6,000 amperes corresponding to an equivalent three-phase short circuit of $2^{1}/_{4}$ million kva is obtained from the bus at Laguna Bell. The bus sectionalizing switch at Laguna Bell is used as a back-up breaker and is equipped with special relays which are timed for selectivity between the test breaker and the back-up breaker. A special program is prepared outlining all switching, relay changes, and other steps in the procedure which is necessary for dispatchers and station operators to know in order to expedite the test. As a result all tests have proceeded without delay and according to program.

As a result of the several tests the following conclusions have been reached:

(*A*). While the major development and research leading to provision of better circuit breakers must of necessity be provided by the manufacturer, the utility has a distinct place in the development of the art through the staging of field tests.

(*B*). While laboratory tests tend to indicate the success of a circuit-breaker design, experience indicates that the final proof of circuit-breaker performance will only come from system tests wherein the switch is required to interrupt its rated current while connected to an operating system.

(*C*). In so far as 220-kv switches are concerned line dropping tests are a necessary supplement to the short-circuit test since some designs which interrupt short circuits successfully are inadequate in some respects when required to interrupt charging currents.

(*D*). While there is some hazard to service incident to the staging of full capacity short-circuit tests it appears that the benefits occurring are of sufficient value to discount the hazard.

(*E*). When phase-to-ground short circuits are cleared in eight cycles or less the effect on consumers service is negligible.

The tests on the vertical-flow interrupter described in Mr. Baker's paper were made at Laguna Bell on October 9 and 16, 1938. The results from the standpoint of system operation were excellent. There was no dip in system speed and no consumer complaints as a result of the tests. Most consumers were not aware that tests were in progress as the flicker of lights which indicated a short circuit was barely perceptible.

A study of the design and results suggests that the vertical-flow principle might well be applied in modernizing existing conventional breakers.

The author is to be congratulated for an interesting paper and another step in the development of high-speed high-capacity circuit breakers.

B. P. Baker: The author is grateful for the interest shown in this paper by the large number of discussions offered. In addition to the many valuable contributions they have made to the circuit-breaker art, some very pertinent questions were asked which I will attempt to answer.

The breaker described in this paper was operated by a standard solenoid mechanism. The effort required to operate it is substantially the same as that required by other high-speed oil circuit breakers. For applications requiring a reduction in control current a pneumatic or motor-operated mechanism may be used.

The energy required to supply the oil flow which is necessary for efficient uniform operation at all values of current, is obtained partly from the operating mechanism which compresses the accelerating springs during the closing stroke. However, at high currents when the pressure in the exhaust chamber rises, this pressure assists to some extent in supplying the energy for the oil pumping action and thus avoids contact stalling or reversal. Actually the amount of oil which has to be pumped is comparatively small since the passage through which it flows is very small. This is not only desirable to conserve pumping energy, but is a natural result of getting the properly controlled relation between the arc and the surrounding oil. This controlled flow of oil in a direction opposite to contact motion, along the entire length of the arc, is one of the factors which make it superior to other longitudinal blast interrupters. It is entirely different in structure and performance from the earlier type of interrupter to which one discusser referred.

From the instant the contacts part, the venting, rate of gas generation, and deionizing processes are controlled rather than waiting for a certain contact separation to release a random amount of stored energy. The motion of the contacts is always against the flow of, and into fresh oil, and not with the blast into regions already occupied by ionized gas. The arc is held in close contact with the oil and gases over its entire length instead of at a relatively short throat. The long narrow arc passage also prevents sections of the arc from burning in relatively quiet gas bubbles. The passage vents into a chamber in which the pressure is controlled, rather than into an open body of oil. Extinguishing action is not dependent on a self-generated gas blast which varies with current.

Careful measurements on the high-speed closing-opening tests indicate that the breaker was probably tripped out before the contacts had reached their full $1^{1}/_{2}$-inch engagement. This would have resulted in a loss of some of the opening acceleration and thus prolonged the arcing time. I have no data which would allow me to conclude that the opening which immediately follows a closing is not affected by it, however, the effect must be small even after a period of four cycles. Certainly after eight or ten cycles the gas from one test should be well away from the upper end of the passage through which the arc is drawn. At one time in the development a check valve was employed at the lower end of the well through which the space under the moving contact was recharged with clean oil during the closing stroke. This was found unnecessary and was abandoned. If Mr. Schwager's fears are justifiable, this solution would undoubtedly solve the problem.

While there were only 115 factory tests represented in figures 7 and 8, actually there were many times that number made on this interrupter and slight variations of it. At 132 kv the recovery rate of the circuit varied from 2,000 volts per microsecond to almost 4,000 volts per microsecond at the higher values of current. At 88 kv it varied from about 1,600 to 3,200 volts per microsecond.

The current transformer is mounted on the floor of the lower porcelain-clad compartment. The low tension leads are brought out through the grounded metal frame by means of small insulators and are very accessible. Access to the transformer itself requires removal of the superstructure, an operation comparable to removing the bushings of a dead tank breaker. However, Mr. Chubbuck in his discussion has made a unique suggestion for removing it entirely from the breaker and thus making the transformer an auxiliary piece of equipment.

It is regrettable that a most valuable but informal discussion by Lloyd Hunt of the Southern California Edison Company was not written for publication. He discussed the field tests in a very detailed fashion, bringing out some interesting points not covered in the paper.

An Improved A-C Pilot-Wire Relay

Discussion and authors' closure of paper 40-127 by J. H. Neher and A. J. McConnell, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 12–17.

H. P. Sleeper (Public Service Electric and Gas Company, Newark, N. J.): This writer made a prediction a few years ago which appears to have been proved incorrect. That fallacy has been further amplified in the paper "An Improved A-C Pilot Wire Relay" by my friends Neher and McConnell. The incorrect prophecy referred to was given as conclusion number two in my paper "Relaying of High Voltage Interconnection Transmission Lines," AIEE TRANSACTIONS, 1933, volume 52. In that paper I predicted that pilot wire relaying would not enjoy much future popularity. However, during the last few years, with the introduction of the Westinghouse type HCB pilot wire relay, and now by the introduction of the General Electric type CPD relay, the popularity of this type of relay has very greatly increased. Furthermore, the increase has proved to be justified due to the very satisfactory operation which has been reported by users of these devices.

The Westinghouse equipment, and the one described in these authors' paper, are sufficiently similar so that the relative merits and differences are minor and do not seem important. Both employ the fundamental improvement over previous pilot-wire systems of using low energy pilot channels so that commercial telephone circuits may be employed. This is of material importance to the operating utilities since the communication facilities are available without capital investment by the operating company and can be abandoned on short notice without withdrawal of the pilot circuit. Furthermore, such channels are usually available at almost an instant's notice, and this is sometimes of importance to the utility.

It is this writer's opinion, based on a very complete laboratory examination and upon a small amount of operating experience, that this type of relay system is fundamentally correct and has been satisfactorily developed by the manufacturers. It should have a very satisfactory operating record and this has been confirmed by the experience to date of a rather large number of operating companies on a considerable number of short transmission line applications.

There still remains the field of longer transmission lines than those at present protected by relays of this type. Present applications are limited by both manufacturers to pilot wires that do not exceed 2,000 ohms or a distance of about 15 to 20 miles between stations. However, there are longer lines which are in the market for protection of this type if the relay scheme can be made applicable. This means that the pilot circuits will be of considerably higher resistance, possibly of the order of 4,000 to 5,000 ohms. Furthermore such circuits, if leased from commercial telephone companies, are usually "loaded," that is, they have a considerable number of loading (inductance) coils in the circuits to improve communication facilities. This increases the a-c impedance of the circuit so that the relay no longer works on a practically noninductive circuit but on one with an inductance of possibly four henries. This of course changes the power factor of the transmitted a-c signal and the relay currents at the two ends of the pilot channel may be considerably out-of-phase. This may be the limiting factor in such an application, as these relays are ordinarily designed to operate on pilot circuits of practically zero inductance. Also, because of the longer pilot circuits, the capacity between wires and to ground is proportionately increased.

There appears to be no fundamental reason why the type of relay described in this paper cannot be made applicable to the longer lines. The relay voltage applied to the pilot wire will have to be increased but the allowable potentials as dictated by the commercial telephone companies appear to be adequate. The effect of the high inductances must be compensated so that the relay currents at the two ends of the pilot circuit are kept approximately in phase. This can be done by means of proper filter equipment which consists merely of series capacitors to compensate the inductance, and parallel inductances to compensate the shunt capacitance. It has been done experimentally by the writer working with the Westinghouse engineers on the type HCB relays. Several applications to lines up to

22 miles are planned by the company with which the writer is connected.

The operating record of these relays will follow directly the service record of the pilot circuits, in this writer's opinion. If the telephone circuit remains continuous and free of faults; if induced potentials are kept below values which will flash protector blocks, which should be capable of accomplishment by means of applying the proper number of neutralizing transformers in the pilot wire circuits; and if the department or the company charged with the maintenance of these telephone circuits provides the proper protection against ambitious or careless personnel who may interfere with these circuits, it is believed that the operating record of these relay schemes will be excellent.

It is especially important that the telephone company leasing these circuits be impressed with the fact that the introduction of foreign potential on these circuits is bound to have serious consequences and cannot be dismissed by a mere "Excuse it, please," which apology is always so gratifying when one has been needlessly wakened by the telephone bell at 2:00 a.m. Education of employees and the co-operation of the supervisors and executives of the telephone company seem to be the answer to this phase of the matter which will so importantly and so directly affect the operating record of these relays. It has been this writer's experience that the telephone companies are, in general, very co-operative and the special telephone rates which are quoted for this service are considered satisfactory.

If the installations of these relays are properly engineered; if the pilot circuits can be controlled directly by the operating utility, or if not, if the full co-operation of the telephone company and its operating personnel can be assured, there appears to be no reason why the operating record of these relays should not equal that of standard relays now in common use on similar applications.

It is the writer's hope that it will not be necessary to reverse this new prophecy.

W. R. Brownlee (The Commonwealth and Southern Corporation, Jackson, Mich.): The use of "standard energy" relay elements with relatively small pilot wire currents instead of the "supersensitive" variety will be welcomed, particularly by those who have experienced trouble with other forms of relays having extremely low energy requirements. Extra sensitive elements are subject to interference from microscopic condensations of matter volatilized from coil impregnating compounds, difficulties with switchboard vibrations, etc. The use of a "current product" element with most of the energy taken from the local source where ample power is available is a fortunate choice.

Some form of backup protection (although probably too slow and insufficiently selective for normal operation) is required with any pilot wire scheme for the following purposes listed in the order of their importance:

1. To clear a fault in an adjacent protected zone when the breaker sectionalizing that zone fails to trip (due to a defective mechanism, open trip coil circuit, etc.).
2. To clear bus trouble from adjacent stations when the bus itself is not separately protected.
3. To provide line protection when the pilot wire equipment is out of service.

The second reason may be removed by installing bus protection and the third may be reduced to a very small value, but the first reason will practically always be sufficient to require backup protection. Such protection will usually involve directional relays, the phase elements requiring a potential supply (inexpensive source such as low tension bus) which will also be adequate for a directional comparison type pilot wire scheme. This situation tends to eliminate one of the three advantages listed by the authors of a differential pilot wire scheme over the directional comparison type.

In some instances the complete immunity of the authors' scheme to an out-of-step condition may be advantageous, although economics will usually limit the length of a pilot wire protected circuit to such a short section that it is difficult for the electrical center of out-of-step condition to pass through the section in a manner to produce false tripping. The use of specially insulated relays is not necessary or desirable for a directional comparison scheme and may be avoided altogether by the use of three-winding neutralizing transformers.[1]

The speed and sensitivity of differential type and directional comparison type of pilot wire schemes are comparable and adequate. When all conditions such as backup requirements are taken into account there is practically no difference in the cost of the two schemes and the choice should then depend primarily upon the over-all reliability to be expected from each. The relay communication system is the heart of the pilot wire protective scheme[2] and the chief engineering disadvantage of the scheme is the hazard of the exposure of the pilot wires themselves.[3] A probability approach to the reliability question indicates, first, that pilot wire circuit trouble should be made practically independent of troubles on the transmission section protected. The use of leased facilities with proper protective equipment does much to accomplish this but brings about an increasing exposure to extraneous influences, both electrical and those brought about by maintenance personnel. The probability approach further shows that troubles due to extraneous sources which are not coincident with power system trouble on the protected section are of little concern provided that (*a*) the relay system is such that extraneous disturbances such as momentary short circuits, open circuits, connection to "test" or "ringing" circuits, will not result in tripping of circuit breakers (in the presence of merely load current) and (*b*) the pilot wire circuit is so supervised that disturbances will be detected immediately and the condition corrected before the relay system is called upon to operate. Over 30 circuit-years' experience with leased pilot wire systems under close surveillance[4] has demonstrated that the surest means of securing adequate over-all reliability is the use of continuous audible and visual supervision of the pilot wire circuit integrity, using current of approximately the same value as is used for operation. This system is even more advantageous where the terminal relay equipment is composed of positive directional elements and direct current relays with wide operating margins found in remote control systems instead of balanced measuring devices of a remote metering system. It is urged that the authors consider a radical increase in the supervisory current of their scheme and that the circuit of figure 8 be modified to include an indication of a grounded telephone protective carbon, permitting such ground to be cleared before a second ground develops, making the circuit inoperative.

I would like to ask the authors the following specific questions:

1. An advantage is claimed for phase angle characteristic of the relay which makes it less responsive to interference from capacitance current. What is the recommended maximum allowable circuit capacitance?
2. Figure 5 shows a maximum pilot wire loop resistance of 2,000 ohms. What is the recommended maximum allowable circuit resistance?
3. In the authors' opinion could the "blind spot" which may occur on rare occasions be avoided by the use of a phase balanced scheme instead of a mixing auto transformer with unequal phase ratios?
4. The authors mention the provision of an adjustable resistor to maintain the ratio differential characteristic of the relay with different pilot wire impedances. Do the authors consider temporary readjustments necessary if emergency rerouting of the pilot wire circuit should increase its resistance by 1,000 ohms or more?
5. It is indicated that as little as five volts loop induction may cause false relay operation. This is a distinct disadvantage compared with direct current schemes in which induced (loop) voltage must be high enough to flash across open contacts to cause trouble. Can this value be raised? What value of d-c voltage across the circuit will cause trouble? What value of standard telephone "ringing" voltage will cause false operation?

G. B. Dodds (Duquesne Light Company, Pittsburgh, Pa.): The Duquesne Light Company of Pittsburgh, Pa., has been interested in, and has used pilot wire systems for the protection of transmission circuits since 1927. Needless to say, we consider the type of protection described in this paper and the type described in a previous article in the *Electric Journal*, November 1935, by Harder and Bostwick, a great improvement over the earlier types, although some of the earlier types are still in service. The Duquesne Light Company has been using since 1934 the same method described in the present paper of utilizing an autotransformer so that one relay and one pair of pilot circuits would give complete protection on a three phase transmission circuit. The relays used, however, were entirely different, and the currents in the pilot circuit were too large to utilize telephone pairs.

We have been using the HCB relay equipment since it became available in 1938, and have been well satisfied with its performance. We were somewhat concerned about the reliability of the telephone pairs, but to date have not had any interruptions to the telephone pairs used for protection, without having a warning beforehand that they would be taken out of service. There have been no failures of the pairs used for protection to date. The telephone pairs used are owned and maintained by our own company. It is recognized, however, that the telephone pairs are the weakest part of this protective system, and some form of backup protection is always provided.

While the high speed operation of the newer type relay systems is usually an advantage, there are some cases where it is a disadvantage. One of these is where it is desired to apply this type of protection to a circuit on which there is tapped load. In some of our cases, the tapped transformer capacity has been sufficiently large that the pilot relays would operate for low tension faults. In several of these instances, we have added overcurrent relays with very inverse time current characteristics. The contacts of these relays are in series with the contacts of the high speed pilot wire relays. By proper choice of current tap and time lever setting of the overcurrent relay, sufficient time can be obtained for faults on the low voltage side of tapped transformers to permit low tension breakers to open, and yet for high tension faults permit clearing in a relatively short time.

In some applications of pilot protection, the minimum fault current may be lower than the maximum load current. This creates a condition whereby an open pilot circuit will cause tripping from load. To prevent this, we have added in some cases undervoltage relays, the contacts of which are in series with the contacts of the pilot wire relays.

Another condition that is sometimes encountered is where the fault current from one end of a circuit protected by pilot wire is relatively small, while from the other end it is relatively large. This means that there is some possibility, with the breaker open at the end from which the large value of fault current is fed, that a fault might not be cleared by the small amount coming from the other end. To overcome this difficulty, we have in some instances installed an auxiliary relay at the substation supplying the large amount of fault current. This auxiliary relay is operated from auxiliary switches in the oil circuit breaker and is closed when the breaker is closed. The contacts of this relay are in the pilot wire circuit between the insulating transformer and the relay. With the breaker open, the minimum fault current that the pilot wire relay at the far end will recognize is cut in half.

T. G. LeClair (Commonwealth Edison Company, Chicago, Ill.): The authors of this paper have described a new pilot wire relay scheme which has the merit of simplicity and quick response. This paper is an indication of an increasing interest in the use of pilot wire relaying in general.

It has been a puzzle to me why a general acceptance of pilot wire relaying schemes has been so slow in this country. Carrier relaying has become quite popular for high speed relaying and yet carrier relaying inherently is more expensive for short transmission lines and is more complicated than pilot wire relaying for the given results.

In Chicago, pilot-wire relaying has been in common use for many years. One of the first references to pilot relaying on the Chicago system was given in a paper by Mr. R. F. Schuchardt in 1917. The diagram of this scheme was published on page 383 of the 1917 TRANSACTIONS, volume 36.

The major advantage of pilot wire relaying is that selectivity is maintained for practically any line arrangement whether one or more lines may be out of service or whether line connections are transferred from one bus to another. A further advantage of pilot wire relaying over carrier current relaying is the direct comparison of relay currents at the two ends of the line. This avoids the necessity for any complicated "out of step protection" to prevent faulty operation due to system instability.

The standard scheme of pilot wire relaying on the high voltage lines in Chicago is illustrated in figure 919 of the Supplement to the NELA Relay Handbook. This relay scheme, which has been in use for about 15 years, is so sensitive that it will operate on a short circuit current materially less than the normal full load current carried on a line. The only limit to the sensitivity of this scheme is the fact that the charging current of the line appears as a fault current to the relays. Therefore, the relay settings must be above the line charging current. The operating time of the relay at both ends of the line is identical regardless of whether the fault current is supplied from one end or from both ends.

The operating record for pilot wire relays on the Chicago system has been surprisingly near perfect. Pilot wire relays are very popular with the men who determine relay settings because they involve no complicated calculations of short circuit currents.

The method described by the authors for obtaining protection on between-phase and phase-to-ground faults with only two pilot wires has certain advantages. On a power system where an impedance is used in the neutral, this scheme makes it possible to have more sensitive protection for ground faults. A very similar method for obtaining this universal protection on two pilot wires is used in Chicago for those lines where more than two pilot conductors are not available. This scheme is also described in the Relay Handbook and illustrated as figure 920.

It is expected that there should be an increasing trend toward pilot wire relaying because this scheme is ideally suited to operation with modern high speed circuit breakers to insure stable operation with heavy transmission line loading.

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): Messrs. Neher and McConnell should be congratulated for the development of this improved relay system. One outstanding feature, I believe, is deserving of more emphasis. I have reference to the fact that they have adapted a standard relay element, which has been proved through several years service to be highly reliable and stable in its operating characteristics, to a service which limits severely the amount of energy which may be applied to the relay circuit. Through the use of the product principle of operation they have made possible the use of such a proved element. While the proof of reliability of any relay system must finally come from the operating records, it does seem reasonable to expect that the results are bound to be successful when the preliminary design effort is directed toward overcoming the limitation, apparently imposed by pilot wires, of using extremely small operating forces. The possibility of pilot wire currents, due to external causes, producing unwanted relay operation seems to be decreased.

Lest someone might think from the mathematical appendices that settling the pilot relay is difficult, it is pertinent to outline how simple the actual process is. It is merely necessary to calculate the minimum ground fault current for a fault at each end with the adjacent breaker open and the positive and zero sequence currents at each end for a ground fault at the far end with both breakers closed. From these current values a few simple calculations give the items needed to use two curves that determine the tap settings required.

To the application engineer there is a lesson contained in the title of this paper announcing "An Improved Pilot Wire Relay" since it implies that pilot wire relaying is an accepted fact. Despite all that has been published in the past twelve years since Fitzgerald[1] announced the first carrier pilot system, it is surprising to find many who still feel that pilot protection is an ideal system but not a practical one. It is not my purpose to discuss the relative merits of carrier versus physical pilot wire systems, nor more specifically the merits of the various systems using physical pilot wires. I prefer rather to call attention to the fact that this is one more paper in a long series covering various methods whereby the equivalent of differential protection can be applied to lines. There is in this literature ample evidence that the methods of protection once considered ideal have for a long time been practical as well. The Relay Sub-Committee in a report prepared two years[2] ago cited operating experience showing the generally good record achieved by all forms of pilot relaying. Since the evidence shows that pilot relaying is past the experimental stage, then the main remaining reason for not using it despite its obvious operating advantages, is one of cost. In this connection it seems to be in order to point out the permanent value of this form of protection. Pilot protection of all kinds may be installed today not only with the assurance that system changes will not require relay system replacement, but also with the assurance that new developments will not make equipment already in service obsolete. This should not be construed as meaning that we have reached the ultimate goal in relay development. The presentation of this paper by Messrs. Neher and McConnell is evidence that development is still going on. What is meant is that new and improved systems of relaying as they are developed will not make necessary the replacement of equipment already in service and giving satisfactory performance. This feature of permanence has been an outstanding feature of the pilot systems of all types introduced since the relatively fast carrier systems of 1932.[3,4]

R. A. Larner (Texas Electric Service Company, Eastland, Tex.): The development of an improved pilot wire relay should be welcomed by operating relay engineers. Where the expense can be justified, a differential scheme of protection for transmission lines is highly desirable.

The later developments, including this one, have tended toward simplification of the problem of applying pilot wire protection. For example, it is now possible to use a single standard relay element operating only on current transformers at each terminal of the line section to protect against the ten different types of faults, usually considered, on a grounded neutral system. The single telephone pair used as pilot wires are operated at relatively low energy levels and provided with supervision equipment.

This development should increase the use of pilot wire relaying. In some instances it may be installed where carrier current protection would have been installed. Under ideal conditions, its performance should practically equal that of carrier current relaying. Carrier current protection is, of course, expected to be more universally accepted in a larger field.

The equipment described appears to have a minimum of contacts, auxiliary relays, interlocks, sealing contacts, etc. Operating experience soon teaches one to appreciate such simplifications, as well as the statement "It is often true that the simplest device also provides the most satisfactory performance." The mixing transformer which is used for reducing to a single electrical quantity from the three phase current transformer circuit, is a good example. It is simply a tapped autotransformer. While it does not provide exactly the same amount of current for similar faults on each phase, it does apparently furnish ample current for use with a pilot wire scheme. At the other extreme, as in the case of a fault near one end, which may have heavy generating capacity, protection to the relay is afforded by a saturating transformer.

It might be of interest to carry out the solution to show the effect of considerable load being carried within the protected section, which in turn might be in part of a loop fed by several plants. Taking as an example such a section on which is located a comparatively large grounding bank near one end of the line: The ground bank would furnish a major portion of the zero phase sequence current at or near its location. The result would be a very meager residual current from the current transformer for internal ground faults, and conversely, a very large residual current for external faults near by.

The authors are to be congratulated on the development of this relay, which evidently constitutes a step in the direction of the ideal relay scheme, including the possibility of separation at preferred points only in case of loss of synchronism. This paper should also be remembered as a valuable reference in a form which makes pilot wire relay information clear and easily found.

R. M. Smith (Westinghouse Electric and Manufacturing Company, Newark, N. J.): A relay of the type described in this paper is indeed an improvement over the older forms of a-c pilot protection using standard overcurrent, differential, or current balance relays. It is a fact that protection engineers throughout the world have recognized the merits of the a-c pilot scheme which compares a single-phase quantity of limited magnitude using only two wires. This statement is borne out by the fact that since the introduction of the type HCB relay in 1937, hundreds of installations have been made both in this country and in many foreign countries. It is quite apparent now that the industry needed this type of relay for the high-speed protection of relatively short lines and that no real solution had existed prior to that time.

We note from figure 6 that the variable-ratio operating characteristic has been incorporated in the design of the relay. This type of characteristic, rather than the constant ratio characteristic of the older forms of differential relays, appears to have some advantages. We found this to be the case in the type *CA*-6 relay for bus differential protection and the type *HA* generator differential relay, both of which were described before the Institute in recent years.

The authors are to be congratulated on their paper, particularly the mathematical treatise for the relay torque equations. However, it is hoped that a thorough understanding of these equations is not essential for the proper understanding and application of the relay.

C. L. Smith (Rochester Gas and Electric Corporation, Rochester, N. Y.): The relay system described by the authors would seem to have at least two advantages over any comparable system with which I am familiar.

1. It employs a single standard element which has given proof of its sensitivity, reliability, and rugged construction in many other applications.

2. The cost should be somewhat less than for previous systems which involved the co-ordination of several standard units or the design of special elements which were not readily applicable to other schemes of protection.

It would seem that this relay system is well adapted to the protection of cable systems where large short circuit currents are common. Assuming that this relay element and auto-transformer have thermal characteristics comparable to those of the power directional induction cylinder relay, we would expect rapid, correct operation over a wide range of fault currents. Our experience with relays utilizing cylinder elements has been quite satisfactory.

If time permits, I would like to ask Mr. McConnell to comment on the application of this relay system to a typical circuit such as shown by figure 1.

Given a maximum to minimum load current ratio of 4/1 and a variation in load power factor from 85 per cent lagging to 85 per cent leading, due to secondary capacitor installations, could tripping of the O.C.B. at the delta-delta bank be accomplished for both phase to phase and phase to ground faults?

The fourth paragraph, page 4 of this paper would seem to indicate that the O.C.B. at the delta-delta bank would not be tripped.

M. A. Bostwick (Westinghouse Relay Engineer, Newark, N. J.): The authors, Messrs. Neher and McConnell, are to be complimented for their novel adaptation of standard elements to a relatively new problem. It appears that the new device should fill the need of a competitive unit for use in the recently revived field of alternating current pilot wire relaying.

There are three principal points that I believe should be commented upon to avoid any misunderstanding:

1. The author's statement, "Yet few applications of relay systems of this type have been made until recently" can be stated in more definite form. Actually, hundreds of type HCB alternating current pilot wire relays have been installed during the past three years. These are giving excellent service on pilot wires up to 30 miles in length.

2. The author's discussion of "blind spots" is quite thorough; however, it may be profitably reviewed. Why limit the definition of a "blind spot" to relay operating failures "at both ends of the line"? Is not high-speed clearing of faults simultaneously at both ends of a line the preferred object of high-speed relaying? Since the watt-meter element described in the paper requires local polarizing, current in each line terminal, it appears that a number of operating failures at one end of the line, or at best a number of relatively slow-speed, sequential operations may be expected. This condition is anticipated when the distribution factors are such that fault current is largely fed in through one line terminal or a low autotransformer output is obtained. The use of a permanently polarized relay element, as in the type HCB relay, would eliminate all of these slow-speed sequential relay operations and actual operating failures that result from a lack of polarizing current at one of the line terminals. Relays of this type (HCB) are capable of tripping both line terminals even though there is no current in one end of the line.

3. The "low autotransformer output," which causes operating failures or slow-speed tripping, may result from an actual lack of current or the peculiar manner in which the various components of current are added in the autotransformer. This is illustrated in the phase *C* to ground diagram of the author's figure 3. The sum of the positive and negative phase sequence current components is shown 180 degrees from the KI_0 vector; tending to cancel the transformer output. This condition may prove troublesome as the division of the various components of current between the line terminals is changed by switching operations on the transmission system. The magnitude of the single phase autotransformer output for phase to ground faults would be considerably improved if the negative sequence current component were omitted and the positive sequence phase "a" component of current were added in its true position, to the product of the ground

current and its multiplier K. By repeating the vector addition, illustrated in figure 3, with these modifications and using a K factor of at least four and with a maximum value of 16, the action of a positive plus zero phase sequence filter may be observed. Such a study will reveal a freedom from the tendency to cancel the single phase pilot wire signal under any conditions, when the multiplier K is set at 16. A tendency toward cancellation will be observed when a "*b*"–"*c*" to ground fault is encountered and K is reduced to 3.9 (the minimum multiplier used in the type HCB relay). With a positive plus zero sequence filter of this type it appears that the single phase output is much less subject to cancellation than the output of the autotransformer described. This is doubly apparent when the frequency with which phase to ground faults is encountered is compared to that of double phase to ground faults.

Both relay systems appear to have adequate zero sequence compensation to avoid these troubles when properly applied. However, use of the positive plus zero sequence filter simplifies the application as only two quantities need to be considered. It also serves to reduce the danger of encountering "blind spots" when applications are made without a thorough study of the system. Furthermore, use of permanent polarization of the relay element assures simultaneous circuit breaker operation on all faults, above minimum trip value, even though the relay at one end of the line is entirely de-energized.

E. E. George (Ebasco Services, Inc., New York, N. Y.): Messrs. Neher and McConnell present an interesting scheme of protection with some new and desirable features. Among these are the use of a polarizing coil to increase sensitivity, a resonant circuit for reducing the effect of extraneous or undesired current, and the use of an a-c relay to take better advantage of phase angle in reducing interference from cable charging current, induced current, etc.

The authors' comment on the effect of the open circuited or short circuited pilot wires may be misleading. The statement about an open circuited pilot wiring preventing tripping and a short circuited pilot wire causing tripping applies chiefly to the scheme developed by the authors. Another a-c scheme which circulates restraining current instead of operating current has the reverse difficulty in case of pilot wire failure. The direct current scheme operates still differently in case of pilot circuit trouble. In some schemes discrimination is lost if the pilot wire is out of service, and it is therefore probable that half of the operations would be incorrect.

This scheme is the second alternating current pilot wire scheme to be presented to the AIEE within the last year or two. Operating experience with a-c pilot wire seems to be generally satisfactory and most users report plans to proceed with additional installations. However, it should not be inferred that the d-c scheme has been superseded. In any a-c scheme one limitation should not be lost sight of. The use of a single relay for phase and ground protection is a compromise—not necessarily satisfactory for either purpose. With a thoroughly grounded transmission system, with a simple transmission tie line, with continuous power supply at each end, and with a circuit breaker at each end, any a-c scheme involves little sacrifice in either phase or ground protection. The a-c scheme is inherently difficult to apply if ground current is limited. In such cases independent phase and ground relays and the use of the direct current scheme may be preferable.

The directional comparison scheme is less likely to trip on load current in case of pilot wire failure, since in any direct current scheme the pilot wire current has no reaction on relay pickup.

Operating experience with a-c pilot wire protection seems to be much like experience with d-c schemes. Troubles experienced have been in the pilot wire circuit or its protection rather than in the relays. Many of us believe that many of the troubles with pilot wire protection could be avoided by close adherence to the principles and practices of circuit protection used by the Bell System and by other communication services. The use of *three winding* neutralizing transformers and of continuous supervision is frequently essential. The use of insulating transformers generally has been much less satisfactory in power company communication service than the use of neutralizing transformers. Satisfactory explanation of this experience may be difficult. Part of the trouble with insulating transformers has been due to the practice of grounding the primary winding. Such ground connections are preferably omitted and if made at all should be connected to earth remote from the power station. On open wire circuits the elimination of grounding is practically essential in preventing frequent blowing of fuses. It is still believed that most of the troubles on pilot wire circuits are due to rise of ground potential at the terminals rather than to induction or other interference along the circuits themselves.

This relay paper is well prepared from the standpoint of presenting to the prospective user information which he needs in considering the application to his own system. Theoretical discussions of relay torque, etc., are necessary but until recently many relay papers omitted other equally important information. No matter how sound may be the electrical design of the relay the prospective user is not likely to be greatly interested unless he finds that the relay has practical features that are satisfactory for some specific application he has in mind. Such features include operating time, burden, minimum pickup current, range of setting, general wiring diagram and simple description of method of operation.

The manufacturers have spent much time and money trying to get a lot of relay equipment into one small case. Pandora had some sad experience with too many things in one little box. Switchboard space is still cheap—and plenty of it should be provided on relay panels.

Most everyone agrees that relay engineers have done excellent work in protecting transmission lines, even where the protection is extremely difficult, but relay engineers have not had enough influence in preventing the design of transmission and distribution systems that are inherently incapable of adequate protection. Some transmission extensions cannot be protected adequately by any known method, regardless of the cost involved, and on some other systems the expenditure for relay protection is all out of proportion and even approaches the cost of additional transmission mileage.

Some system planners and budget committees are allergic to high voltage circuit breakers. It is difficult to understand why high voltage circuit breakers are sometimes not provided on long transmission lines costing $5,000 to $10,000 per mile and where the cost of breakers is relatively small compared to the over-all cost and to the increase in firm power supply which they provide.

There is an increasing need of information on relay protection that would outline the fundamental principles and limitations of relay protection in a manner *understandable and convincing* to electrical engineers who do not specialize on protection but who are responsible for the planning of most of the facilities a relay engineer has to protect.

L. L. Draper (Bureau of Power and Light, Los Angeles, California): There are two questions that I would like to ask the authors regarding the scheme of pilot wire protection outlined in this paper:

First, is there any objection to connecting the center point of the pilot wire winding on the insulating transformers to ground other than the effect this may have on the pilot wire supervisory schemes? And second, can this type of protection be successfully supplied to a three-terminal line in which the through short-circuit current may be equal in two of the terminals with their sum flowing in the third terminal?

In regard to the first question, if grounds can be applied at both ends of the pilot circuit then any induced potential in the pilot wires or difference in ground potential at the two ends will cause equal currents to flow in the same direction in the two pilot wires and return through the earth. These currents should not affect the relays but would cause the potential to be consumed in impedance drop around the loop instead of concentrated between the pilot wires and the cable sheath at the two ends of the pilot cable.

It is believed that if this plan of grounding the pilot circuit is feasible a great many existing communication cables could be used for pilot wires that would otherwise be unsuitable because the potential difference between the conductors and sheath would be sufficient to flash over the protective gaps and short-circuit the pilot wires.

E. L. Harder (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In 1937 there was introduced into the relay art, "A Single Element High Speed Pilot Wire Relay," called the HCB, reference number 2 of the current paper. While a distinct field was envisioned for such a device at the time, it must be admitted that its widespread acceptance and application are beyond the most optimistic predictions. It is believed that the large number of installations of pilot wire relaying since the introduction of the HCB indicates not only a particularly successful design but also a distinct trend in the industry toward this form of protection. There evidently was a pent-up need for such an addition to the relay family. It is not surprising, therefore, to read of this paralleling development as described by Messrs. Neher and McConnell. It is encouraging to know that they feel, as we do, that high speed pilot wire relaying has come to stay.

Looking back over the course of this development it is difficult to mention any one application factor which more than others has led to the increased use of pilot wire protection. Some of the outstanding factors are as follows:

(a). Fast simple protection of the short interconnecting lines in metropolitan areas of utilities and power lines of industrials has made possible fast clearing, and clean-cut selectivity, and has avoided accumulating of relay times.

(b). The scheme is universal and does not require individual study of each particular line section, or accurate predetermination of currents or voltages.

(c). The economic upper limit of pilot wire protection, originally considered to be 10 to 15 miles, is found in many cases to be 40 to 50 miles, depending upon the circumstances. This is due partially to the existence of privately owned telephone lines for which the charge to relaying services is comparatively small and partly to the existence of certain high voltage cable circuits which do not lend themselves to the application of carrier current relaying. In other cases where a cable must be installed for communication purposes, the incremental cost of pilot wires for relaying is quite small.

As to the particular form of relay, the circulating current arrangement was adopted for the HCB after consideration of the various possibilities, including the balanced-voltage arrangement utilized by the present authors. ("Circulating Current" refers to the circulation of restraining current over the wires during through-fault conditions as compared with "Balanced Voltage" in which voltages at the two ends are balanced against each other over the pilot wires for the through-fault condition.) The "circulating current" arrangement used in the HCB is entirely free from the effects of switching transient which the authors indicate they have had to reduce by going to a resonant circuit.

Operation based on total fault current with the HCB is considered to be a desirable operating feature since it assures simultaneous operation at the two ends of the line and makes it possible to supply intermediate tapped loads right up nearly to the value of total internal fault current setting.

J. H. Neher and **A. J. McConnell:** The authors are somewhat overwhelmed by the extent of the discussion which this paper has evoked. In the limited space available, therefore, we must restrict our concluding remarks to certain general points which have elicited the most discussion and forego the answering of many of the specific questions which have been asked.

We are gratified to know that many of the discussers concur with us in the belief that pilot wire protection, and particularly that of the a-c type, now represents an accepted reliable method of transmission line protection. The hundreds of such relays which have been mentioned as having been placed in service during the past few years are mute evidence of this point.

As one discusser has pointed out, the procedure for setting the relay is as simple as the relay itself. It is only the equations describing the performance which appear to be complicated.

The application of any pilot wire system to a three-terminal line, to a line from which a considerable load is tapped, or to a line in which there is a large grounding bank, often presents insurmountable difficulties and this relay is not a panacea in this respect. Within limits, however, the relay may be applied in such applications. In regard to applications on lines terminated in a delta-connected bank, it will be evident that the relay at that end cannot respond to certain types of single-phase-to-ground faults, though the fault will be cleared by the operation of the relay at the other end.

As has been pointed out, there is no fundamental reason why relays of this type cannot be used with pilot wire distances greater than the figure of 2,000 ohms, which was given in the paper merely to represent the upper limit of normal short line application. For longer pilot wires the pick-up current of the relays will be increased roughly in proportion to the square root of the pilot wire resistance. There will also be an inherent phase angle shift due to either or both the pilot wire capacity and inductance if "loading" is employed. This may be compensated for by the use of a suitable network or, in some cases, by suitable changes of the relay constants or adjustments.

The stated value of 5 volt loop induction as affecting the relay performance is again a nominal value, and in most instances 15 volts will not cause false operation. However, even 5 volts is very high in telephone practice and no difficulty should be experienced in keeping below the figure. The magnitude of the induced voltage necessary to cause trouble can, of course, be raised at the expense of desensitizing the relay. D-c voltage in the pilot wire will not cause trouble, though it must be realized that there must not be a resultant current flow of sufficient magnitude to affect the operation of the insulating transformers. This may be prevented by introducing capacities into the pilot wire circuit. The introduction of "ringing" voltages will not affect the operation of the relays unless the frequency of the ringing voltage coincides with the power system frequency.

The matter of grounding of the pilot wire circuit depends largely upon the particular conditions at hand. In some instances, the midpoints of the pilot wire windings of the insulating transformers can be grounded. In general, however, such grounds are preferably omitted. If it is essential to reduce the voltages between the pilot wires and ground, the use of neutralizing transformers is believed to be the most satisfactory method.

In regard to pilot wire supervision, we feel that the monitoring system should be designed to best fit the particular conditions at hand and considerable latitude in respect to the circuit of figure 8 is permissible. The relay described in the paper lends itself readily to the use of neutralizing transformers. The d-c monitoring system would be applied in shunt at both ends through suitable filter reactors and the flow of d-c monitoring current is blocked out of the relays by the capacitors already incorporated in the relays.

The correlation of back-up protection with the fundamental protective scheme has been rightly stressed. We agree that in cases where a high speed directional-controlled back-up system is deemed to be necessary, the directional comparison system of pilot wire protection may be preferable despite the attendant complexity of auxiliary relays and contacts. We are more inclined to the belief, however, that where a simple a-c type of pilot wire protection can be expected to give reliable service, the complexity of the back-up protection can be correspondingly reduced, and often the directional feature can be omitted altogether.

Several discussers have indicated that they have obtained satisfactory results from the use of an autotransformer or equivalent circuits in order to obtain a simple electrical quantity for any type of fault. This and the method of vector rotation and addition (or phase-sequence components) are apparently the only two methods which have been used to accomplish this result. Admittedly, both systems leave something to be desired. One system is weakest against single-phase-to-ground faults and the other against two-phase-to-ground faults. Despite the greater frequency of occurrence of the former type of fault, which under certain conditions may cause sequential operation of the relays utilizing the autotransformer method, we feel that this is more than offset by the fact that under certain two-phase-to-ground fault conditions, neither of the relays may operate where the other method is employed. Also, the autotransformer method is considerably simpler and does not require the use of a supersensitive relay element.

It also seems to us that the questionable advantage of "permanent polarization," in order to trip the circuit breaker at the distant end of the line under exceptional conditions, is more than offset by the disadvantages entailed of incorrect operation by surges introduced into the pilot wire circuit, such as have been caused by the discharge of the capacitor associated with the monitoring circuit through accidental short-circuiting of the pilot wires. Polarization at power system frequency will prevent operation from such causes as well as from frequencies other than that of the power system.

The relative merits of the opposed voltage and circulating current systems have been discussed. This is a question long unsettled, and which goes back to the early days of pilot wire protection before these modern systems operative over telephone-type pilot wires were developed. Both systems have their advantages, and a choice between them is largely a matter of preference. Possibly future experience with the modern systems will determine the answer.

Displacement and Diffusion in Fluid-Flow Arc Extinction

Discussion and author's closure of paper 40-115 by Joseph Slepian, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941 (April section) pages 162–7.

D. C. Prince (General Electric Company, Schenectady, N. Y.): In discussing this very interesting paper, agreement should be noted at the outset with the statement that after circuit-breaker performance has been calculated, such calculations should be supported by thorough-going tests. That is undoubtedly the basis upon which all good engineering rests, and the air-blast breaker is no exception. The remainder of the paper does not altogether follow this well-established engineering principle. The rest of the Introduction, section I, is devoted to the varied opinions of European investigators.

Section II is devoted to the discussion of an "ideal" fluid-flow nozzle. To the extent that such a nozzle can be made "ideal," one would not expect the circuit to be interrupted at all since there would be a thread along axis Z in the figure not influenced by the fluid flow. The fact that such breakers do operate is evidence that in practice these "ideal" conditions do not exist, and such a departure from the "ideal" can be easily verified by suspending the thread along the axis Z. During the discharge of air, the thread will be found to be in violent agitation, thus bearing conclusive evidence that the "ideal" is not being reached or even approached. There is no evidence that if the "ideal" were realized, it would bear any given relation to the interrupting properties of the design.

In section III, Dr. Slepian goes on with his discussion but, as before, they are not calculations leading to a numerical result or reports of tests indicating that the calculations were correct.

In section IV, second paragraph, we find the statement that, "Photographic records show that the thickness of this column is too great for simple diffusion or thermal conductivity to account for the high interrupting capacity actually found." Apparently, in following his diffusion theory, a dilemma has developed which has to be explained away. The author goes on to indicate that the boundary layer between the splitters and the air flow would be expected by theory to be of the order of "a few thousandths or a hundredth of a centimeter thick." Such dimensions would be far too small to be observable in the photographs, and, further, if the boundary layer is of such dimensions, it would in no way interfere with the operation of the circuit breaker on the displacement theory.

Later on, in this same section, Dr. Slepian speculates that gas projected from a gas-forming wall will widen the boundary layer enormously. Even if this should happen, and there is no evidence of its happening in the present paper, it would not appear to have any special bearing on the conclusions as to whether the arc is interrupted by displacement or diffusion.

In section V, Dr. Slepian calls attention to the fact that there is a trail of luminous gas instead of a clean break shown in the Biermanns' photographs. This trail is doubtless evidence that with the symmetry which is shown in figure 1, there is a tendency for hot gases to linger along the axis of the nozzles, but again this has no special bearing on the point at issue.

Later, in referring to figure 6, the author attributes to a certain 2-inch length of arc responsibility for the interruption. He holds this belief in spite of the photographic record. The first break in the arc in the photographs referred to occurred at the edges of the splitters. It would not seem to be important which parts of the luminous gases were first blown away thereafter.

Section VI appears to deal entirely with an endeavor to show that the limitations of the simple diffusion theory recognized in section IV might be removed by assumptions allowing a hundredfold increase in the thermal effects. The author has, therefore, overcome the rather serious shortcoming that he recognizes in his own theory, but even that does not appear to be evidence why his theory should be accepted in place of the displacement theory against which he has shown no evidence.

It is not as if there were no straightforward criteria by which it is possible to determine whether interruption is by displacement or diffusion. The process of diffusion is one in which the arc products are cooled and deionized. Such a cooling and deionizing operation can be measured by its effect on arc drop, that is, anything that is done to intensify cooling and diffusion will also increase the amount of arc drop, and that can be observed on the oscillograph. The displacement, on the other hand, does not operate until current zero, and therefore has no inherent relation to arc drop. Careful analyses show that air-blast circuit-breaker performance is substantially independent of arc-drop properties.

Another method of observing the relative importance of diffusion versus displacement, would be to make a structure which would promote diffusion. Such a structure might consist of a large number of barriers transverse to the arc, which would tend to break up the arc, produce eddies in the air blast, and markedly increase diffusion effects. It may be observed that although such structures are in use in low voltage, magnetic blowout circuit breakers, they are not present in the transverse air-blast circuit breakers of the companies producing such breakers. Diffusion effects would be accentuated were the splitters indicated in figures 2 and 3 full of holes. It will be observed that this is not done in the air-blast breakers now produced.

On the whole, it appears that the weight of evidence favors the displacement theory as developed by calculations and supported where necessary by critical tests. Under the circumstances, the fact that the displacement theory is also simple should not be held against it.

W. F. Skeats (General Electric Company, Philadelphia, Pa.): Dr. Slepian is to be commended for attempting to set on paper a critical comparison of the displacement and diffusion theories of arc extinction. He has shown how such considerations as (1) the difference in density between the hot gases of the arc and the relatively cool gas surrounding it, and (2) the emission of gas from the barriers enhance the diffusive effects in the region of the arc to a considerable extent. These same considerations, however, have aspects in which they strongly reinforce the displacement theory, and in a critical comparison these aspects should be given their full weight.

One of these aspects is well brought out in connection with the flow in the double nozzle of figure 1 of the paper. Dr. Slepian quite correctly points out elsewhere in the paper that the gases of the arc proper will have a density less than one twentieth that of the surrounding cool gas. This is a greater discrepancy than exists between water and mercury. In this situation, the heavier fluid, entering the nozzle with radially inward flow, must obviously be expected, on account of its greater inertia, to tend to maintain this direction of flow. The lighter fluid would experience the fast changes in velocity, moving very rapidly in an axial direction away from the central point O so as to make room for the influx of the heavier fluid. Thus a break in the continuity of the lighter fluid may very well be expected notwithstanding the contrary indications of calculations based on the assumption of equal densities.

A similar squeezing out process is to be expected in the region of the barrier tips when the cross blast is used. It is in this connection that Dr. Slepian points out the wide disparity in velocities, but he does not continue to the logical consequence that the fast-flowing hot gas will be rapidly scavenged from the region of the barrier tip. The evolution of gas from the barrier itself also plays an important part in interruption by cross blast. It seems manifest that this gas must push the arc away from immediate contact with the barrier and interpose a layer of gas between. This gas is largely hydrogen and therefore has an extremely low viscosity. Thus it will tend to form the thin boundary layer which, in Dr. Slepian's own words, ". . . would not seriously change the conclusions of the displacement theory."

In section V, Dr. Slepian refers to photographs taken from a high-speed moving picture record presented by Prince, Henley, and Rankin, stating that he believes these include the moment of circuit interruption on the test in question. In connection with this record, however, the desirability of having a definite indication was appreciated, and this was provided by placing in the field of the camera an auxiliary spark gap which was broken down by the recovery voltage. A record of its breakdown was carried on the cathode-ray oscillograph along with a record of the recovery voltage itself, so that the interval between current zero and gap breakdown could be accurately determined. Counting back the proper number of frames from gap breakdown then gives the frame at which current zero occurred. Unfortunately this was four frames after the last of those selected by Dr. Slepian. Thus conclusions based on Dr. Slepian's frames are open to considerable revision.

These considerations, perhaps, do not prove the displacement theory, but they do effectively refute those conclusions of the paper which state that the displacement theory is impossible or is contradicted by motion pictures.

Hugh L. Dryden (National Bureau of Standards, Washington, D. C.): Under the conditions prevailing in gas-blast circuit breakers, there is no doubt that the transport of matter, heat, and ions by turbulent diffusion is much greater than by molecular diffusion. The writer has given elsewhere[1] a review of recent developments in the experimental and theoretical aspects of turbulence in relation to the process of diffusion, which contains a more complete discussion of some of the points mentioned below.

No experimental data are available as to the values of intensity u' and scale L to be expected in the presence of the high speeds and large temperature differences occurring in the arc. The values assumed by Dr. Slepian are not unreasonable. For isotropic turbulence decaying in an air stream of constant speed the changes of L and u'

with time are given approximately by the relations

$$L\frac{d\left(\frac{1}{u'}\right)}{dt}=0.2$$

and

$$\frac{1}{u'}\frac{dL}{dt}=0.2$$

For $L=0.1$ centimeter and $u'=3\times10^4$ centimeters per second, the decrease in u' and increase in L are about six per cent in the first microsecond. Hence the initial large values would remain fairly large for an appreciable time even in the absence of further generation of turbulence.

In any quantitative estimate of diffusion, the "mean free time," which is of the order of magnitude of L/u', plays an important role. For $L=0.1$ centimeter and $u'=3\times10^4$ centimeters per second, the mean free time is of the order of three microseconds. For time intervals small in comparison with the mean free time, the diffusing quantity spreads at a uniform speed proportional to the intensity of the turbulence and the diffusion is not dependent on the scale. For times large in comparison with the mean free time, the diffusing quantity spreads in accordance with the usual diffusion equation with a coefficient of diffusion equal to l_1u', where l_1 is a length defined by $\int_0^\infty R_t dt$, R_t being the correlation coefficient between the speed of any particle at any instant and the speed of the same particle after a time interval t. For turbulence behind a grid, G. I. Taylor found that l_1 was approximately one-half L.

If the intensity of the turbulence in existing commercial devices is actually of the order of the acoustic velocity, there is not much hope for improvement of performance by increasing the turbulence. It might be expected that the device shown in figure 4 would be considerably improved by admitting the air through a series of jets or through an annular nozzle directed from the side toward a point just above the lower electrode. The impingement of the streams of air from different directions should produce an intensity of turbulence much greater than that produced by the arrangement illustrated in figure 4.

J. Slepian: The discussion from so eminent an authority on aerodynamics as Dr. Dryden is certainly most welcome, since the questions at issue in my paper are essentially aerodynamical. Dr. Dryden's published papers have been wonderfully helpful to me in trying to understand in more detail how rapid flow in the gas may aid in arc extinction, and I must express here my appreciation of them. It is most reassuring to me that Dr. Dryden finds nothing obviously wrong in my paper, and believes that the numerical values I used are not unreasonable.

I am highly gratified that Mr. Prince agrees with the analysis in section II of my paper. This is really sensational news! Pure streaming in a frictionless fluid *cannot* interrupt the continuity of an arc! We are now all agreed on this. This is because (second paragraph of Mr. Prince's discussion) "there would be a thread along axis Z in the figure not influenced by the fluid flow." The arc interruption does take place in an actual fluid having friction because, "the thread will be found to be in violent agitation." But this is only another way of describing the turbulence which I also emphasize.

Now that we are in agreement on this very fundamental point, no doubt Mr. Prince will want to modify his simple equation for a-c arc extinction in a flowing fluid, since that equation used only the velocity of pure streaming, which we now agree can play only an indirect part in interrupting the arc. No doubt, Mr. Prince will want to use the intensity of the "violent agitation" of the arc column in his modified equation. Since this intensity is not a simple function of the streaming velocity, but depends on the viscosity of the fluid, and the shape and character of the walls of the channel in which the fluid is accelerated to its high streaming velocity, I am afraid that the modified equation will no longer be simple. I am very sorry for that. Mr. Skeats even suggests that the ratio of the densities of the arc gas and the surrounding fluid will need to be considered, which means that the properties of the arc itself will have to enter into the modified equation. Again that is too bad. The simple equation needed to know nothing of the nature of the arc. "The arc with its varying gas composition, varying pressure, uncertain temperature, varying conductivity, unknown state of ionization, etc., is merely swept away!"

Mr. Prince again confirms his basic agreement with me in the sixth paragraph of his discussion where he states that "with the symmetry which is shown in figure 2, there is a tendency for hot gases to linger along the axis of the nozzles." No doubt, then, Mr. Prince will now want to modify figure 2*a* in "Circuit Breakers for Boulder Dam Lines," ELECTRICAL ENGINEERING, April 1935, page 368, and figure 13 "The Oil-Blast Circuit Breaker," AIEE TRANSACTIONS volume 50, 1931, page 511, to take account of this tendency for hot gases to linger along an axis of symmetry. Also, I am sure he will want to introduce this lingering tendency into his modified simple equation.

The harmony of the agreement between Messrs. Prince, Skeats, and myself is, however, broken when we try to pick out the frames including the moment of arc extinction in those most remarkable high-speed pictures shown in "The Cross-Air-Blast Circuit Breaker," D. C. Prince, J. A. Henley, and W. K. Rankin, AIEE TRANSACTIONS, volume 59, 1940, page 510. In paragraph seven of his discussion, Mr. Prince seems to choose the frame which first shows a break in the arc at the edge of a splitter. This would be frame 6. In my discussion of these pictures, in the present paper I have chosen frames 17, 18, and 19. Skeats, on the basis of oscillographic evidence not given in the paper, selects frame 23.

I was much puzzled by the break in the arc continuity first shown in frame 6, because it occurred while the arc was quite intense, and because it did not grow in length in the succeeding frames, and because it closed again in frame 11, and reopened in frame 13, again not changing in length in succeeding frames. I suspected that this break was not real, but only apparent, and perhaps due to parallax of the various pinholes of the camera with respect to the barrier edge. I wrote to Mr. Prince then, asking about this, and received a reply confirming my interpretation. I therefore chose frame 18 as the first which showed any authentic break in the uniformity of the arc.

Mr. Skeats, apparently, has a cathode-ray oscillogram which he has not submitted along with his discussion, in which one point is correlated with frame 30. By counting back in time on the oscillogram, Mr. Skeats picks frame 23 as showing the moment of arc extinction. However, the oscillogram is undoubtedly one showing the voltage across the arc space, and not the current through the arc. There is a matter of interpretation, however, in picking the moment of substantially zero arc current from the voltage oscillogram. If this was done as is suggested in figure 5 of "The Cross-Air-Blast Breaker," I would not agree with it, but would choose a somewhat earlier time. It is very probable, then, that if I had Skeats' cathode-ray oscillogram before me I might still choose frame 18 as the one showing arc extinction.

Possibilities and Methods of Extending a Carrier Current Relay Channel to Other Uses

Discussion of paper 40-129 by R. M. Smith and S. L. Goldsborough, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 23–7.

F. M. Rives (nonmember; General Electric Company, Philadelphia, Pa.): This paper is devoted entirely to a subject which has often been mentioned in the past, but which has not been given the publicity that it perhaps deserved. The fact has long been known that some pilot relay channels, and in particular, carrier relay chanels, are standing idle all but a small fraction of the total time, and that there is, therefore, a possibility of obtaining multiple service from the channel.[1] The fact that carrier channels are particularly easy to adapt to multiple uses has been previously mentioned both in American and European papers.[2,3,4] Operating practice has made general use of this possibility, to signal for checking purposes and for communication when making routine tests. More limited use has been made of carrier channels for the purposes described in detail by Messrs. Smith and Goldsborough.

It is gratifying, therefore, to see a paper dealing exclusively with the possible extensions of the relay channel, as in this way more direct attention is brought to this possibility. The economic advantage of being able to provide several functions for little more expense than would be required for any one alone certainly would seem to justify the authors' suggestion that the expense be evenly distributed between the several services involved.

In order to obtain the maximum dependability and at the same time a reasonable cost, carrier-current equipment designed principally for relaying must necessarily be fairly simple and therefore limited in many respects. Although, as indicated by the authors, there are a number of additional functions that can be supplied by a simple keyed carrier-relay channel, additional functions or channels obtained by tone modulating the carrier may involve requirements and complications that cannot be met with the conventional relay-type equipment.

One tone-modulated channel may possibly be provided with only the addition of a tone-generating source at the transmitting end and a suitable demodulator, filter, and relay arrangement at the receiving end. When more than one tone-modulated channel is desired, or when tone-modulated channels are desired in addition to a voice-communication channel, it is rather questionable whether conventional relay-type carrier equipment can be used. Complex arrangements for shifting the voice frequency channel, or "cutting holes" in the voice channel would appear to depart considerably from the limited facilities provided in the relay-type equipment.

One of the principal limitations in all relay equipment is in the small modulation range provided. Using control-grid modulation, high-level modulation can only be obtained by a large reduction in normal or unmodulated carrier output. Some improvement in this respect may be obtained by using screen or plate modulation, but for all practical purposes the relay equipment must be considered essentially as designed for low-level modulation. While fairly satisfactory emergency-type telephone communication can be provided with low-level or negative modulation, tone-modulation channels require good modulation characteristics, and if elaborate filtering is to be avoided, each tone channel has to be set up to modulate the carrier at a minimum of 15 or 20 per cent. For several simultaneous tone channels, or for a combination of tone and voice channels, a modulation-percentage range must be provided for the sum of the peak modulation percentages used on each channel.

Another important limitation in the conventional relay equipment is in the lack of an adequate automatic volume control in the receiver which is required in multi-channel tone-modulated systems to deliver to the de-modulating and filtering equipment essentially constant signal levels with varying high tension line attenuation.

The most practical means for overcoming these limitations and providing highly reliable channels by tone modulation essentially requires high-grade communication-type carrier equipment. As an example of what can be done in this line, a recent application that is being installed on a new mid-western 220-kv circuit provides a separate carrier channel in each direction with eight tone channels on one carrier and six on the other.

One important method of providing an additional channel with conventional relay-type carrier equipment was not mentioned by the authors. This is the carrier-shift scheme in which the transmitter frequency at one end is shifted a small amount to actuate a relay associated with a special heterodyne receiver at the other station. A very successful installation of this nature has been in operation in Canada for some time in which the shifted carrier signal is used to provide remote tripping of breakers. This feature is provided in addition to the usual pilot relaying and telephone communication. An interesting feature of this arrangement is that the remote tripping has complete preference over all other functions and the tripping signal can be originated or received at any station regardless of whether or not the channel is being used at that point for telephone or telemetering.

The authors have indicated that in some cases, due to system conditions, the relays may be unable to take control of the channel because at the point under consideration no relay action would result. This writer is familiar with an installation of this type which has now been operated successfully for several years with joint relaying and "point to point" telephone where the carrier transmitter was under the joint control of the main carrier relays and additional simple, undervoltage relays. Certainly if there is no possible infeed to a fault under certain conditions the fact that a fault does exist can always be indicated by the voltage failure.

From the foregoing points, it may be concluded that when it is desirable to perform several simultaneous functions or set up several channels over a single carrier circuit it is usually more practical to use communication-type equipment than to load too much complication on conventional relay equipment that is fundamentally designed for much simpler, but still exacting applications.

Capacitors and Circuit Performance

Discussion of paper 40-126 by J. W. Butler, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941, pages 408–15.

C. E. Arvidson (The Commonwealth and Southern Corporation, Jackson, Mich.): The timeliness of this paper is evident from the claims made by some engineers as to how they have improved the voltage regulation on circuits by the installation of uncontrolled shunt capacitors. It is encouraging to note that Mr. Butler brought out the fact that such installations do not reduce voltage regulation—they merely raise the voltage level. This review of the fundamental principles involved in the application of shunt and series capacitors should be helpful in bringing about a better understanding of these problems.

W. K. Boice (General Electric Company, Schenectady, N. Y.): This paper should be of particular interest to those engineers who wish to acquire a good understanding of the application of capacitors. The several accompanying figures illustrate many important points. For actual application work, engineers will find the fundamental diagrams of figures 5 and 11 most useful. This fundamental approach is applicable to a variety of conditions which could not be covered by any of the numerous graphs and tables which have been prepared on the subject of capacitor application.

Engineers interested in capacitor application may desire to refer to the following papers which have not been included in the author's bibliography:

A Double-Break Oil- or Gas-Blast Power Fuse

Discussion and author's closure of paper 40-134 by G. Leslie Hill, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941, pages 402–07.

A. C. Schwager (Pacific Electric Manufacturing Corporation, San Francisco, Calif.): Mr. Hill has to be congratulated for the successful development of a novel type fuse. Arc interruption in oil circuit breakers and fuses follow identical laws and since the series-break oil-blast breaker has shown an improvement over the conventional explosion chamber breaker, it is but natural to expect the series-break fuse to have advantages over the conventional single-break oil—or expulsion fuse.

Mr. Hill's design has the advantage that the interrupting arc is initiated only after the first arc has accumulated a sufficient volume of gas, independent of the current flowing through the fuse. Uniform interrupting performance is thereby guaranteed over the entire current range, including the smallest currents.

With the present trend in indoor equipment away from oil, the double-break oil-immersed fuse described might be considered a special application. The dry-type fuse however appears to have definite possibilities. Its success will of course depend on commercial considerations. The design seems to be considerably more expensive than that of the conventional expulsion fuse with universal fuse link which is capable of interrupting currents of several thousand amperes.

If the range of the fuse described by Mr. Hill could be extended to include currents in the order of 10,000 or 20,000 amperes, it might replace some of the present designs of powerhouse fuses.

G. Leslie Hill: A. C. Schwager brings out that arc interruption in oil circuit breakers and fuses follow identical laws. The author agrees that there is a corollary existing between the two types of circuit-interrupting equipment. This is especially true when one considers a comparison between the modern breakers where a tank of oil or air is maintained under pressure for utilization in circuit interruption, and the double-break fuse. In the case of the circuit breakers, the oil or air to be used is stored under pressure for use when needed. The energy used for building up the pressure in the tanks is derived from any convenient source, whereas the energy for storing up the pressure in the chamber of the double-break fuse is derived from the fault current in the circuit to be interrupted.

In regard to the use of the dry-type fuse indoors, it must be remembered that the use of a power fuse indoors (either dry or liquid type) calls for some means of cooling or deionizing the expelled gases during circuit interruption. A condenser was developed for use with the double-break fuse during the original experimental work on this device. It was applied to the fuse when filled with a liquid or a dry arc-extinguishing material. It was also applied to the plain expulsion fuse. This condenser, with modifications in the design is also used on the spring-actuated, glass-tube, liquid-filled fuses and the dry-type boric acid, spring-actuated, fuse devices, manufactured by two prominent fuse manufacturers in the United States.

It was pointed out in the text that the double-break fuse was in an intermediate class as to costs, circuit-interrupting duty, etc. It is only obvious that the design is more expensive than the conventional plain expulsion fuse with a universal fuse link, but there are certain disadvantages such as the hot expelled parts and the long arcs, inherent in the plain expulsion fuse, that some operating men do not desire, therefore it is necessary to pay a small additional amount for a higher class device. I wish to point out very specifically that the universal fuse link cannot be used successfully in a *glass expulsion tube.*

The author is positive the range of current interruption of the double-break dry-type fuse may be extended to equal the oil-filled fuse or even extended to a higher value by changing the mechanical structure of the cartridge and the fuse tube. These changes would increase the cost and when it is considered that the present interrupting capacity meets approximately 90 to 95 per cent of our requirements, it is very questionable that any changes increasing the cost would be warranted. Since the double-break fuse was developed, there has been placed on the market, a spring-actuated, cartridge-refill, dry-type fuse that is built especially to cover the higher bracket of power requirement such as station service. These devices have an organic fuse tube, are larger and stronger and are built for heavy duty service and obviously cost considerably more than the fuses described in this paper.

In regard to a verbal question about what arc-extinguishing substance is used in the dry-type fuse: At the present time we are using granular dolomite (marble) which is obtained at a convenient ore mill. Its chemical analysis is approximately $CaCO_3$ 60 per cent and $MgCO_3$ 40 per cent. When the double-break fuse was first developed, various dry-type arc-extinguishing substances were tried out such as baking soda, baking powder, magnesium carbonate, boric acid, and marble, with chlorate of potassium and gun powder mixed, at certain times, in the above substances.

In the liquid-filled fuse, oil and carbon tetrachloride were used and more recently water has been experimented with. Water has been substituted, for the dry granular filler, in the 7-inch and 14-inch refill cartridges, and very interesting results have been obtained. The following table gives some comparative arc times obtained during tests using the 14-inch, 60-kv, refill cartridge.

	Dry Granular Filler			Water Filled
Current Interrupted RMS Amps.	Total Arc Time (Cycles)	Primary Arc Time (Cycles)	Secondary Arc Time (Cycle)	Total Arc Time* (Cycle)
1,700	2.0	1.10	0.9	0.55
3,300	1.4	0.80	0.60	0.50
4,300	1.0	0.50	0.50	0.40

*The primary and secondary arc times could not be distinguished on the oscillograms.

Power-Factor Testing of Transformer Insulation

Discussion of paper 40-130 by J. B. Hodtum, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941 (January section) pages 28–30.

H. S. Endicott (General Electric Company, Pittsfield, Mass.): Although much time has been spent on the problem no single test has yet been devised which, when applied to the terminals of a transformer, will indicate unmistakably the condition of the insulation. The correct analysis of test data still requires a large amount of personal judgment and experience with insulation both in laboratory samples and in factory apparatus. Any new methods of analysis, therefore, warrant serious consideration.

Capacity or charging current readings sometimes have been used as an indication of the condition of insulation. They have the disadvantage that comparison with previous readings is necessary before any conclusions may be drawn. A single power-factor reading on the other hand has considerable meaning (at least in the light of experience). When a series of readings is taken, as in drying out a transformer by short-circuit heat run, capacity may give exactly the same indication as power factor. In the case of a drying run recently made by the writer the curve of capacity as a function of time of drying was the same shape as the power factor curve.

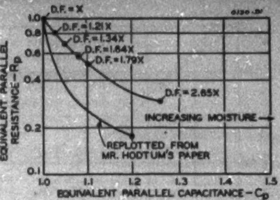

Figure 1. Relation between R_p and C_p for constant temperature and increasing moisture content

Curves for this transformer, in both the wet and dry condition, have been plotted in the same manner as those presented by Mr. Hodtum, except that the equivalent parallel resistance, R_p, is plotted on a logarithmic scale. Mr. Hodtum's curve is re-drawn for comparison. This shows that the sharp break in the curve of R_p against C_p is due partly to the use of a linear scale for R_p in Mr. Hodtum's paper. Some flattening of the curve is to be expected since it has been found that the first small amount of water taken up by dry cellulose is held so tightly that its dielectric constant may be as low as 20. Otherwise the curves are quite similar to Mr. Hodtum's although the moisture content was only in the range of 10 to 15 per cent. It is remarkable that Mr. Hodtum obtained such a small change in dissipation factor when his insulation had taken up 40 per cent water.

It would be desirable to have more data covering transformers with various types of

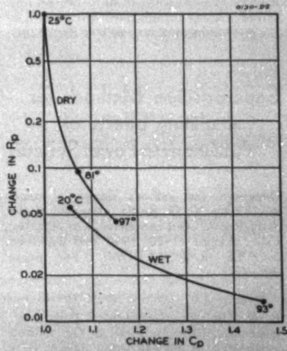

Figure 2. Relation between R_p and C_p for constant moisture content and increasing temperature

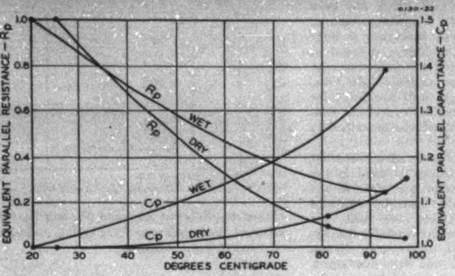

Figure 3. Change of R_p and C_p with temperature

insulation and with known moisture contents. Such data probably already exist in the files of some of the operating companies and we may look forward to having them presented.

A. H. Foley (General Electric Company, Pittsfield, Mass.): It is of interest to note that Mr. Hodtum makes frequent reference to the equivalent shunt values of capacitance and resistance in dielectrics. While our experience has shown equivalent shunt values to be of no great significance at low dissipation factors, they are more representative of the dielectric at high dissipation factors.

As pointed out by Mr. Hodtum, capacitance bridges, in general, express dielectric characteristics in terms of equivalent series capacitances and resistances. In line with this it might be of interest to some to know that the General Electric Company developed a capacitance bridge in 1934 which expresses dielectric characteristics in terms of equivalent shunt values directly. Several such bridges have been in constant use in our factory since that time and have proved the superiority of the bridge method for measurement of dielectric characteristics. For the benefit of those interested in the subject an article is being prepared which describes the network in these bridges and shows how the arrangement can be used in the measurement of transformer insulations.

Superposition Methods for Calculating Effects of Additions to Power Systems

Discussion and author's closure of paper 40-133 by V. G. Rettig, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941, pages 396–401.

E. W. Kimbark (Northwestern University, Evanston, Ill.): In view of the limited availability of a-c calculating boards it is not surprising that attention should be given to the improvement of "longhand" methods of solving networks. Although such methods can never compete economically against calculating boards for carrying out comprehensive studies on complicated networks, it is equally true that the calculating board can never supplant longhand methods for simple problems or simple networks. The present paper helps to extend the field of useful application of longhand solutions to more complicated networks than heretofore.

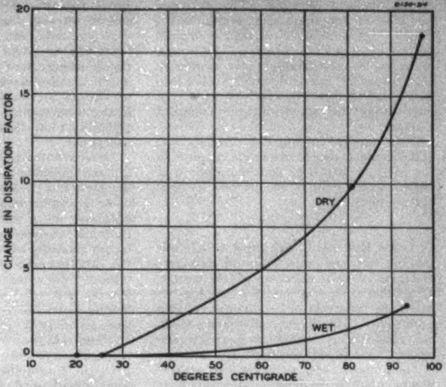

Figure 4. Change of dissipation factor with temperature

The principal features of the method of network solution advocated in the paper may be summarized as follows:

1. The assumption of constant-current loads in preference to constant-impedance loads.

(*a*). Because it more correctly represents power-system loads, and

(*b*). Because it is easier to calculate.

2. The superposition of currents and voltages of

(*a*). An original condition, as determined from readings of station instruments, and

(*b*). Corrections obtained by an algebraic solution of the network of lines.

The present paper by Rettig and the paper on successive approximations by Smith (listed in the bibliography[3]) when taken together make available a practical system for the longhand solution of almost any power network. Smith assumes constant-impedance loads, and in this respect his method is inferior to that of the present paper. But I wish to point out that Smith's method of successive approximations can supplement the method of the present paper in three ways: (1) in determining the currents and voltages of the original operating condition, if data on line impedances and loads are available, even though the necessary instrument readings cannot be obtained; (2) in calculating the correction currents and voltages if the network of lines is at all complicated; (3) in accurately representing any load characteristic, whether constant kilovolt-amperes or otherwise, if the assumption of constant-current loads is not accurate enough, by successive approximations in which constant-load currents are assumed during each step.

Edith Clarke (General Electric Company, Schenectady, N. Y.): It is generally recognized that the calculation of current and voltage distribution in power-system networks is a laborious task. For cases where new loads or circuits are added to an existing network, the superposition methods given by Mr. Rettig simplify the problem, in that calculations are made of *changes* in values of currents and voltages from known initial values and not of the total currents and voltages. The assumptions made, the degree of precision obtainable, and the limitations of the method are clearly stated, thus making the method readily available for problems in which the degree of precision obtainable is adequate.

However, solution of problems of the type given in the paper can be obtained to a high degree of precision on an a-c network analyzer, without the necessity of approximations or simplifying assumptions. For this reason the a-c network analyzer when available will usually be preferred. To those who do not have access to an a-c network analyzer, the methods given in the paper will be of especial interest and value; moreover, they can also be used to advantage for estimating purposes by those who do have such access.

A. A. Kroneberg (Southern California Edison Company, Ltd., Los Angeles, Calif.): Problems of voltage regulation on complex electrical networks have always troubled engineers confronted by them. There is no lack of theoretical material in textbooks and periodicals on network solutions. However, the scarcity of articles such as V. G. Rettig has presented may lead one to believe that there is too big a gap between pages of textbooks and the notebooks of practicing engineers confronted with practical voltage problems.

We appreciate the author's proof that assumed constant currents more nearly represent conditions on an actual system rather than assumed constant impedances. Our comments are chiefly directed to the author's statement that "any method which would permit the elimination of some of the impedances from consideration would greatly simplify any solution." It is our opinion that the simplification lies in the

elimination of components of load currents in various lines rather than the reduction of number of impedances. Thus in voltage calculations on the system of the Southern California Edison Company, the methods of matrix algebra were used in preference to the method described by the author. In the matrix method, the line currents are not considered and line impedances are transformed into a set of self and mutual impedances of the network-to-load currents.

Figure 1 shows an impedance matrix of 15 substations interconnected by 22–66-kv transmission lines with a supply station (Laguna Bell) where the voltage is regulated. Any current vector may be assumed for load taken from the network at each substation. The voltage drop from the supply station to each substation is then a summation of *IZ* drops in the corresponding row after all columns have been multiplied by the assumed load current vectors. It has been found to be helpful to plot voltage gradients for each set of assumed load currents as shown in figures 2 and 3. Figure 2 shows the voltages at various substations of figure 1 under actual load conditions. Figure 3 illustrates the addition of a 50,000-kva synchronous condenser at Chino. It is merely necessary to multiply the column marked Chino by the additional vector current of the synchronous condenser and add vectorially the resultant impedance drops to the vectors of voltage drops computed for figure 2. Added loads can be computed in a similar manner.

There is little labor saving between this method and the one described by the author when a relatively simple network is studied under a single set of assumed currents. When a more complicated network is analyzed under any number of load conditions, the matrix method results in a very appreciable saving of time.

V. G. Rettig: The discussions by Professor Kimbark and by Miss Clarke are very much appreciated since they help to more accurately define the field of application of the methods described in the paper. Frequent use for these methods has been found, however, particularly on what might be classed as the medium capacity circuits with voltages of 13.2 to 66 kv on the Cincinnati Gas and Electric Company system. As pointed out by Professor Kimbark, successive approximations based on the paper by Mr. Smith can be applied to the final results obtained by superposition methods if superposition methods are not considered to be sufficiently accurate.

The author's statement, referred to by Mr. Kroneberg in his discussion, that the elimination of some of the impedances from consideration greatly simplifies a solution refers to line or load impedances or both. The author had in mind in particular the elimination of all load impedances leaving only line impedances to be dealt with. This also is the method followed by Mr. Kroneberg in his example since he calculates the various mutual and self impedances from line impedances only and sets them down in matrix form.

Mr. Kroneberg apparently makes one approximation in setting up the matrix that the author has not used and that is—all mutual and self impedances are represented at the same phase angle. For the general power network made up of cables, transformers, and overhead lines, this assumption may lead to large errors. To avoid this, the network could be represented by two matrices, one for the resistances and one for the reactances, but the work of setting up the original matrices would be more complicated as would the solution for final voltage drops.

It should be noted also that Mr. Kroneberg has considered the calculation of voltage drops only and has not indicated how current division in the various lines that make up the network would be found. The example given applies to the calculation of the effects of changing loads on a given network of lines, but if any line additions or changes are made a complete new matrix must be set up which may add considerably to the work to be done.

The use of matrices will, in certain cases however, provide a good method of obtaining complete solutions for a variety of load conditions. Case I described in the paper makes use of only the self impedances represented in the matrix and gives the change in voltage directly only at the point where the load is added or changed.

Some Acceleration Tests on Large Synchronous Pump Motors

Discussion and author's closure of paper 40-120 by Raymond W. Ager, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941, pages 416–22.

A. H. Lauder and C. E. Kilbourne (General Electric Company, Schenectady, N. Y.): Professor Ager has presented a very interesting account of acceleration tests made on laboratory machines and on installed large synchronous pump motors. While it has long been possible to test laboratory machines and to make factory tests on large motors, field tests on machines of this type have been infrequent, though not impossible. Professor Ager's apparatus and method are therefore a distinct advance in the art of field testing of acceleration characteristics.

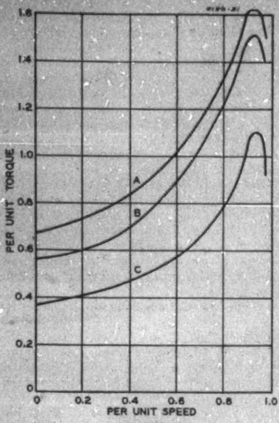

Figure 1

A—Accelerating speed-torque characteristic, 100 per cent voltage at motor terminals

B—Installed accelerating torque characteristic curve *C*, figure 14

C—Calculated accelerating speed-torque characteristic, 100 per cent voltage at switching station

This is quite desirable, as accurate checking of the performance of electromechanical drives can now be accomplished on the assembled unit. Previously, motor characteristics have been matched with the expected characteristics of the mechanical drives and checks on the combined units have seldom been made, particularly if the operation of the unit was generally satisfactory.

Professor Ager's method will be particularly valuable when used in combination with existing methods for determining the desired torque characteristics of motors. This can be done by co-ordinating factory tests and field tests. Factory tests are generally made by the measured power input method, usually under reduced voltage, and data corrected to full voltage. While this method admittedly contains some errors in making corrections, the largest error to be expected, that of saturation, is usually quite small because even under full voltage the internal flux of a motor during its acceleration period is less than that same flux during normal operation. If the data obtained (either by present factory methods or by Professor Ager's method, which also contains an assumption, namely, that rate of acceleration does not affect torque) on the machine without connected load, is combined with data obtained after installation, so that the acceleration characteristics of various types of loads can be better known, then Professor Ager's method will perform its greatest service.

In order to co-ordinate data gathered at different places and under different conditions, the terminal voltage must be known, and when an external impedance comparable to the motor impedance exists between the motor terminals and a point of fixed voltage, either that impedance, or the current drawn by the motor, must be known. Therefore, the usefulness of the tests obtained can be considerably increased if simultaneous oscillograms of voltage and current are taken with the acceleration film.

It is interesting to compare the results obtained by Professor Ager with factory tests and with calculated performance data on one of the large synchronous motors. In figure 1 curve *A* is the 100 per cent motor terminal voltage-torque characteristic, determined by factory test, on the motor whose "installed" test characteristic is given as curve *C* of figure 14 of the paper. The system on which the motor operates has considerable impedance between the motor terminals and the generated voltage. Due to the arrangement of the system it is not desirable to regulate the generated voltage to hold 100 per cent voltage at the motor terminals in any individual pumping plant, but rather to regulate voltage at a central switching station. Curve *C* of figure 1 shows the motor torque characteristic calculated from the 100 per cent voltage characteristic, curve *A*, assuming that 100 per cent voltage is held at the switching station and including the impedance between the motor terminals and this station. It is observed that the "installed" characteristic, curve *B*, falls between curves *A* and *C*. Obviously, if the motor is operated on reduced voltage, curve *B* should fall below curve *A*. Its divergence from curve *C* can be explained by several hypotheses. The system was very lightly loaded when these tests were made and therefore the voltage at the switching station may have been in excess of 100 per cent. The actual impedance between the switching station and the motor terminals may be slightly less than the calculated impedance on which curve *C* is based. Probably a combination of these two reasons is more nearly true.

Professor Ager's tests also give interesting indications of the manner in which the large motors synchronize. If the number of swings made just prior to synchronism are counted, it will be found that figure 7 indicates zero acceleration four different times, figure 10 three different times, and figure 13, neglecting the final swing caused by switching interruption, three times. Figure 10 indicates an earlier attempt of the motor to synchronize than was the case in figures 7 or 13. Possibly field application took place at a lower speed in this instance than in either of the other two. Therefore, since the torque characteristics of all motors are similar, more nearly identical performance of unit number 2 would be expected if the field application relay were set to apply field at a higher speed.

J. V. Kresser (Westinghouse Electric and Manufacturing Company, San Francisco, Calif.): Professor Ager has presented an interesting method of obtaining speed-torque curves of motors under actual load conditions. Obviously, this method is applicable to any type of motor but should be particularly useful in obtaining points between start and pull-out for induction motors, and between start and pull-in for synchronous motors.

Figure 2 of Professor Ager's paper is of particular interest since it is the first time to the writer's knowledge that a measured speed-torque curve of a three-phase motor with single-phase secondary has been published, although Wagner and Evans[1] published one which was calculated and Lamme[2] published one which was obtained by qualitative analysis. Some very interesting results may be obtained from operation with single-phase rotor. In a case investigated by the writer, the motor would not accelerate beyond half speed when started with resistance in only one phase of the rotor (a frequent procedure for medium size motors), even at light load, and vibrated excessively. Analysis of symmetrical components revealed that the torque curve had a cusp which became negative at a slip of about 0.5 and the magnitude of the double-slip frequency-torque pulsation was about 50 per cent greater than the average torque.

This is but one case of the many where heretofore a large part of the speed-torque curve has not been obtainable by tests but has to be calculated, involving complex and tedious calculations, especially for unbalanced or unsymmetrical circuits. In these cases Professor Ager's method will be of great advantage, consisting as it does of a comparatively simple test followed by simple computations.

One disadvantage of the method is the scattering of points obtained as synchronous speed is approached. This may often necessitate drawing the acceleration-time curve to an extended scale in order to obtain average acceleration and torque. However, there is also a benefit resulting from this scattering of points and that is the clear picture obtained of the character and magnitude of the torque pulsations.

It is quite evident that the method can be made quite accurate with care by using a long, well-centered scale, large timing disk, and a constant frequency source for the stroboscope and timing disk. It constitutes a valuable addition to the several existing methods of obtaining speed-torque curves with the great advantage that comparatively simple tests can be made in the field under actual load conditions which cannot very often be duplicated in the field.

Raymond W. Ager: The torque pulsations recorded in the tests perhaps need some further comment. The complications which they add to the calculations are slight once the causes and effects are understood. All pulsations recorded had frequencies equal to twice the slip frequency. Therefore at 50 per cent speed the time required to complete one torque cycle was equal to $^1/_{60}$ second or the time which elapsed between pictures. At 75 per cent speed the torque cycle was completed in $^1/_{30}$ second while at $83^1/_3$ per cent speed it required $^1/_{20}$ second or 3 cycles of the 60-cycle supply. We may use these facts in locating the curve. At 50 per cent speed each reading is the average of one complete torque cycle. At 75 per cent speed we must average two successive readings. At $83^{1}/_{3}$ per cent speed we must use the average of three readings, etc. Where the reading interval is not every film but, to use examples from the paper, every fourth film as was done for figures 10 and 13 or every fifth as for figure 7, then the method of calculation automatically averages these pulsations at $87^{1}/_{2}$ per cent and 90 per cent speed respectively, and at all multiples of the corresponding slips. A partial averaging is obtained at all other speeds except synchronous speed. Only as synchronous speed is approached is the full value of the pulsation indicated.

The process of pulling into step of the synchronous machines is indicated in the curves. Other curves showing this process in greater detail may be drawn from the data obtained in the tests. This operation at Eagle Mountain was relatively simple due to the high ratio of pull-in torque to pulsating torque. This machine nearly locked into step at 14.3 seconds, it then slipped a pole and locked into step smoothly with the application of the field at 14.8 seconds. The last small negative swing represents hunting after locking into step or it may have been introduced by timing errors of the equipment.

The motor at Iron Mountain had relatively a higher value of pulsating torque. This motor pulled into step, actually going a small fraction of a per cent above synchronous speed, at 6.3 seconds on what appears to have been a combination of reluctance torque and the effect of induced rotor currents. The polarity being reversed the field breaker did not close. Upon the decay of these rotor currents the reluctance torque was not sufficient to hold the motor in step and it slipped a pole. If this interpretation is correct it would substantiate the contention of Messrs. Lauder and Kilbourne that the rate of acceleration may effect the torque. The exact time of field application is not definitely shown by the curves but is believed to have been at 6.5 seconds.

The conditions at Gene were slightly more complicated. The motor was within one per cent of synchronous speed at 7.9 seconds but this motor like the other two happened to come up to speed on this start with reversed polarity. It therefore had to slip a pole, which it did between 8.0 and 8.5 seconds. It then started to slip a second pole, but at 8.7 seconds the field breaker closed pulling the motor back into step.

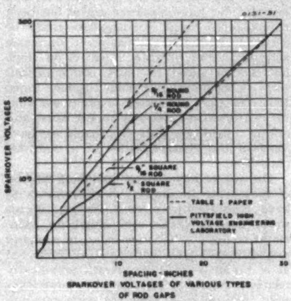
Behavior of Point Gaps at 60 Cycles

Discussion and author's closure of paper 40-131 by J. V. Lebacqz, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 44–8.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper is an interesting contribution to the subject of point-gap sparkover. The author's curves of figure 2 show very consistent readings of gaps 1, 3, and 7 for all spacings up to about the standard humidity of 15.4 millimeters. I would like to ask what deviations from the average curves were observed for separate test points?

The author's results for gap number 5 ($^{9}/_{16}$-inch square rod ended by a section perpendicular to its axis, vertical gap) check the results obtained in the laboratory with which I am connected with $^{1}/_{2}$-inch square rods mounted horizontally at spacings of 17 inches and higher. At lower spacings the author's values are higher as shown in figure 1 by the lower dotted line, for instance at 8 inches by 18 per cent. The difference at lower spacings probably is due to the difference in mounting of the gap. In my tests the gap was mounted with the rods at a specified height, H, above ground where $H=(1.3S+4 \text{ inches})\pm 10$ per cent with definite specifications for the overhang of the rods beyond the supports ($S=$ spacing). It should be noted that during calibration tests no attempt was made to keep the electrodes clean. Lower values than presented in the paper were obtained contrary to the author's results whose tests indicated higher values when the gaps were not cleaned.

The same figure confirms that a round rod has a higher sparkover than a square rod as shown by the author's results for gap number 2 ($^{9}/_{16}$-inch round rod ended by a section perpendicular to its axis), upper dotted curve, and by the curve for a $^{1}/_{4}$-inch round rod, upper solid curve. From these differences it is clear that very definite regulations have to be followed when a rod gap is used for voltage measurements.



SPARKOVER VOLTAGES OF VARIOUS TYPES OF ROD GAPS (CUT PERPENDICULAR TO THE AXIS)

Figure 1

Mr. Lebacqz obtained a straight-line change of sparkover voltage with humidity for all gaps and all spacings. He observed also a definite change of relative influence of humidity with gap spacing. This latter change checks results obtained in my laboratory although the straight-line variation at least for the larger spacings does not.

The following discussion applies only to square-cut rod gaps mounted according to AIEE Standards. Figure 2 shows the correction factor obtained for different gap spacings as function of absolute humidity. Because these curves were taken several years ago, humidity is expressed in grains per cubic foot. However, a scale is added expressing humidity in millimeters Hg. These curves are a result of a study of humidity effect carried out under normal conditions of humidity and air density during the course of about a year. The deviation of single-test points from the average was about equal for all gap spacings and was of the order of plus or minus three per cent at standard humidity and as high as plus or minus seven per cent at humidity of 20 millimeters Hg.

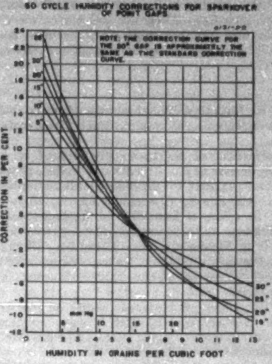


Figure 2

On the basis of the correction factors thus obtained, a comparison of change of sparkover voltages with humidity is as follows for the 30-inch gap (gap number 5):

Table I. Kilovolts Sparkover

Humidity Millimeters	From Paper Figure 2e	This Discussion
10	282	276
15	296	292
20	312	298

It is probably worth-while to point out that humidity corrections at humidity higher than standard (6.5 grains per cubic foot, 0.608 inch Hg or 15.4 millimeters Hg) are usually very unreliable as has also been observed during the author's tests at least at the large spacings. In closing, I would like to ask the author whether, on the basis of his research, he considers some forms of point gap usable as a reliable instrument for measuring voltages? As he states in the introduction, "Arc-over voltages of point gaps in air have been considered rather inconsistent and difficult to reproduce with reasonable accuracy." I am still of that opinion and would much prefer the sphere gap for voltage measurements. Other factors, of course, such as impulse sparkover and time lag enter into the picture to a large extent, when a gap is considered as a measuring instrument, and the sphere gap, of course, is much more reliable all around, especially since its sparkover voltage does not change with humidity. As a matter of fact, rod gaps were used for several years as the yardstick for testing transformers with impulses. Their use now is as a wave-chopping device, while the cathode-ray oscillograph is used as the voltage-measuring device.

P. H. McAuley (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The author has made a useful investigation of sparkover phenomena in a very fertile field. Attention is called, however, to a paper not listed in the bibliography which is as near to a classic on the subject of the effect of humidity on flashover and sparkover as has ever come to our attention. This is Fielder's paper "Humidity Effects on Flashover of High Voltage Apparatus" which appeared in the *Electric Journal* in December 1935.

The effects of electrode shape on sparkover voltage was forcibly brought to our attention about twelve years ago when Mr. Hodnette of our Sharon works and I were obtaining widely different results in the calibration of rod gaps. The standard co-ordinating gap had not appeared at that time and it developed that one of us was using a half-inch square rod, and the other a half-inch round rod, both square cut. When the situation was discovered, the square rod was adopted and further investigation dropped. We were dealing with spacings up to ten inches and it was not appreciated that electrode effects with the round rod extended to the large spacings indicated in the paper.

The influence of electrodes is indicated by the shape of the sparkover curves published by different authors as well as those standardized by the AIEE-NEMA committee on insulation co-ordination. The rate of change of slope at short spacings is neither uniform nor consistent. Similarly, the erratic behavior of the standard rod gap is shown by the bands which it was found necessary to introduce to cover the data from different laboratories for impulse tests. For positive waves the band extends from five to nine inches spacing. For negative waves a band appears between 10 and 23 inches spacing. There is no thoroughly satisfactory explanation of why these bands occur or of why they occur at these particular ranges.

It is our opinion that the author may be giving a little too much weight to electrode condition. After observing the vagaries of high-voltage sparkover for many years, it is felt that many of the phenomena are due to unaccountable conditions in the dielectric rather than to the electrodes. Similar occurrences to those reported in the paper have been observed on apparatus such as bushings where the arc does not necessarily occur from the same point on successive applications. Also, it has been noticed many times in impulse tests where the voltage is raised in small increments that when the first flashover occurs, the voltage must be lowered several per cent to stop flashover. In other words, after the first flashover a somewhat lower voltage will continue to produce flashover, but previous to the first flashover, this same lower voltage can be applied indefinitely without flashover. A flashover apparently leaves a semipermanent effect either in the dielectric or on the electrodes.

On the other hand, with the sphere gap it is often the practice to disregard the first 60-cycle sparkover in any series of tests. It is often much lower in voltage than succeeding applications.

Similarly, the day-to-day changes would seem to indicate the effect of some unknown conditions in the dielectric rather than on the electrodes. The tests in the paper were made in a confined space and it is possible that some of these phenomena may be more pronounced, on this account, than if the tests were made in an open laboratory or outdoors.

Concerning the effects of humidity, the curves in the paper do not extend below ten millimeters of mercury vapor pressure. Bellaschi and McAuley (AIEE technical paper, 40-92) have shown that the absolute humidity for indoor and outdoor laboratories is below ten millimeters (0.4 inch) for all but about four months of the year. Consequently, a great deal of laboratory testing is done at humidities lower than the range covered in the paper. Fielder also observed both that the effect of humidity is lower at short gap spacings and that the effect decreases at high humidities. Because the paper covers only the shorter gap spacings and the higher humidities, the author's results should tend to be lower than if the more practical ranges of humidity and spacings were investigated. Also, the tests reported were made in a chamber with a conducting floor and ceiling. It is not stated whether the test gap was halfway between floor and ceiling. We have observed and it has been reported by other investigators that the effect of humidity on flashover decreases and sometimes becomes negative in slope for certain dielectric field configurations such as bushings and point-to-plane gaps. It is, therefore, desirable to point out that the arrangement with a metal floor and ceiling might possibly approach or have some of the characteristics of a point-to-plane gap.

The author has used an ingenious method of measuring humidity, which appears to have considerable merit. Fielder, in his work, used a Leeds and Northrup automatic recorder. This consisted of wet and dry resistance-type thermometers connected in a bridge circuit to record graphically relative humidity. Absolute humidities were then obtained with the corresponding dry bulb readings.

In the concluding paragraph of section 4, some hints are given which suggest further investigations of a very promising nature. The observation that ether vapor increased sparkover voltage by 17 per cent seems to support our suggestion that unknown conditions in the dielectric cause many of the inconsistent results. An isolated observation of this nature often points the way to a broad fundamental investigation which results in great progress in a given field.

J. V. Lebacqz: In his discussion, Mr. McAuley questions the exact position of the gap in the test chamber. The author regrets that in the description of the equipment he did not make it clear that the gap was halfway (within plus or minus three inches) between floor and ceiling of the test chamber. Since the length of electrode protruding from either floor or ceiling was at least 4$^1/_2$ feet, it seems difficult to assimilate such a setup to a point-to-plane gap.

Concerning the range of humidity and spacing studied, the author observed, during the whole period of the study, only two or three days when the humidity dropped below 10 millimeters Hg pressure, the minimum observed being about 7.5 millimeters Hg. Decreasing the humidity below the ambient value was not considered practical, and the author had to satisfy himself with considering only the range reported in the paper. As to the spacing, it was considered desirable that the dimensions of the test chamber be at least three times the length of gap under test in order to avoid external influences on the field shape between the points. This means that the volume of the test chamber increases as the cube of the maximum gap length considered, and had the gap length been doubled it was feared that difficulties would be encountered in obtaining a homogeneous mixture of the water vapor in the air.

It is quite obvious from the results obtained in this study that changes in the dielectric, as well as the shape and the surface condition of the electrodes, will affect the breakdown voltage and the behavior of point or rod gaps. The author did not wish to give the impression that he underestimates the influence of the dielectric but rather that he believes that both surface and dielectric condition will affect the field shape, upon which, in the final analysis, the breakdown voltage will depend.

The author sincerely appreciates the interesting discussion sent in by Mr. J. H. Hagenguth, containing a comparison with the results obtained by the General Electric high-voltage laboratories. Answering the question raised in the first paragraph, the author wishes to state that the deviation from the average curve for separate test points for clean electrodes (1, 3, and 7), on the same day, did not exceed one per cent, and for at least seventy-five per cent of the points, 0.5 per cent (refer to figure 1 of the paper). However, average curves taken on different days might have differed by as much as three per cent (refer to paragraph "Other factors affecting arc-over voltage" of the paper).

Referring to the end of the second paragraph of the discussion, the author wishes to point out that his tests "indicated higher values when the gaps were not cleaned" for the special case of electrodes ending in one well-defined point (1, 3, and 7) and at small spacings. Because of burning no effect was noticed for gap number 5.

Referring to figure 2 of Mr. Hagenguth's discussion, the author wishes to point out that he does not see any reason for the sudden change in slope in most of the curves at the standard humidity of 15.4 millimeters Hg. No such change was observed in this work, especially not for the square-cut square rod gaps, where all the test points fall within ±1.5 per cent of the average curve for spacings of 18, 24, and 30 inches, at all humidities up to 25 millimeters Hg. Unreliable results at large spacings and high humidities were obtained for all electrodes except the square-cut $^1/_2$-inch square rod.

The author wishes to close these remarks by considering the suitability of some forms of point gap as a reliable instrument for measuring voltages under steady-state conditions (i.e., 60 cycles or direct current).

It appears to him that the main qualities of a voltage-measuring gap should be reliability, insensitivity to surface conditions, and facility of duplication. These requisites are not, in his opinion, found in the sphere gap. Many spurious arc-overs, especially at large spacings, make the results less dependable than could be desired. The sphere-gap arc-over voltage is also highly dependent upon surface conditions; any scratches, rough spots, or pitting due to previous arcs will materially decrease the values obtained, and any deviation from the ideal sphericity will alter the results between different sets of spheres. On the other hand, the tests reported in the paper seem to indicate that the square-cut square rods give results practically independent of surface condition and show no tendency to extremely low or extremely high values of arc-over. The author cannot agree with Mr. Hagenguth's statement that "the sphere gap, of course, is much more reliable all around, especially since its sparkover voltage does not change with humidity." He does not see how this independence from humidity would make one gap more or less reliable than the other. It simply means, to him, that, if rod gaps are used, two correction factors ought to be introduced (air density and humidity), while for sphere gaps only the air density has to be considered. The author thinks, however, that the addition of a second correction factor would be a small price to pay to avoid the use of a voltage-measuring instrument which is not only very expensive to acquire but also very difficult to maintain in perfect shape. Of course, more work covering a wider range of voltages would have to be done before a definite answer could be given to this question, but the author feels that there is a possibility that, provided reliable correction factors were determined, some form of point gap might prove a more accurate method of measuring voltages than the sphere gap.

The author is in complete agreement with Mr. Hagenguth that other factors such as impulse sparkover and time lag enter the picture. He wishes to state again that all the preceding discussion does not apply to impulse phenomena, where the cathode-ray oscillograph used in conjunction with a good voltage divider is probably the most accurate and reliable method of measurement.

Braking Magnets for Watt-Hour Meters

Discussion and authors' closure of paper 40-128 by I. F. Kinnard and J. H. Goss, presented at the AIEE Pacific Coast convention, Los Angeles, Calif., August 27–30, 1940, and published in AIEE TRANSACTIONS, 1941, pages 431–9.

G. J. Wey and V. S. Thomander (Westinghouse Electric and Manufacturing Company, Newark, N. J.): This paper makes quite clear the influence of metallurgical and magnetic aging in connection with the stability of permanent magnets. The reported findings agree very closely with data obtained by the Westinghouse company particularly in connection with the chromium steels.

Granting a suitable treatment for obtaining metallurgical stability, it is interesting to note the influence of demagnetizing methods upon the magnetic aging. The difference in magnetic stability for the two positions can, no doubt, be accounted for by the degree of uniform demagnetization obtained by either the parallel or normal field. In addition to the influence of demagnetizing methods on magnetic stability under conditions of heat cycles, we have found that the methods in like manner have considerable influence upon stability under conditions of external field surges. The surge stability obtained by either of the two methods of coil demagnetization discussed is highly sensitive to the direction of the external field surge applied. However, demagnetization obtained by passing current directly through the center of a magnet largely eliminates the directional effect of the applied external field surge and at the same time reduces the magnitude of the resulting change in damping due to the surge.

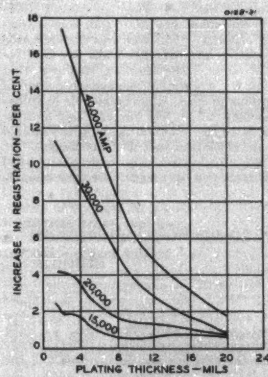

Figure 1. CS—Permanent magnet effect of plating thickness on resistance to current surges

Considering the influence of demagnetizing methods on both magnetic aging and stability under surge conditions, we have found it highly desirable to avoid coil demagnetization wherever possible.

Referring to figure 11, the authors' tests on the various magnet material were obtained on simple bar magnets. While this method gives valuable data for drawing curves of demagnetization versus coercive force, the results cannot be applied directly to show the merits of practical designs since the demagnetization, particularly of chrome magnets, is also a function of the shape of the test magnet. In all of our work we have used standard magnets.

We are surprised to note that the authors obtain such good results from a 0.002-inch thick coating of copper on chrome steel. Curve *A* on figure 11 shows a performance practically as good as Alnico II.

In connection with investigations of surge effects, which led to our recently adopted practice of electroplating magnets, tests were made to determine the effectiveness of varying thicknesses of copper deposition.

The appended curve shows the shielding effect for various thicknesses of copper plating from a minimum of two mils to a maximum of 20 mils. A thickness of about eight times that indicated by Goss and Kinnard (0.015–0.018) was adopted for the standard product, thus retaining the use of chrome steel on which there exists a wealth of experience with regard to permanency in actual practice.

The authors state that the effectiveness of the copper plating is reduced by the inability to build up a coating in the exposed air gaps. Our tests have shown that as long as the external surfaces of the poles are shielded it is not necessary to build up a coating on the working air gap surfaces.

Paul MacGahan (Westinghouse Electric and Manufacturing Company, Newark, N. J.): After reading the excellent paper on "Braking Magnets for Watt-Hour Meters," which was presented by Kinnard and Goss, it seems to me that much of the interesting bibliography record of previous investigations has been omitted. I have reference especially to the following:

THE MAGNETISM OF PERMANENT MAGNETS, **S. P. Thompson.** *Journal* Inst. of Elec. Eng. (British), February 1913.

This carries a very extensive bibliography.

COBALT MAGNET STEEL, **P. H. Brace.** *Electric Journal*, March 1929.

PRINCIPLES GOVERNING CHOICE AND UTILIZATION OF PERMANENT MAGNET STEELS, **R. L. Sanford.** Bureau of Standards Paper No. 567, December 1927.

MAGNETIC PROPERTIES OF STEELS, **Madam Sklowdowska Curie.** *Bulletin* de la Societe d'Encouragement Year 1898, reprinted in *London Electrician*, page 28, year 1898.

This remains as probably the most important contribution to the science of permanent magnets ever made, and is certainly the groundwork of all the modern progress which has been made.

Before Madam Curie published her epochal paper, there were numerous experimenters in the field, attracted to the problem even as now, for producing instruments or meters. Among these the most notable ones in America were Edward Weston, pioneering in this field previous to 1887, Elihu Thomson in 1889, and O. B. Shallenberger in 1888. These early experimenters preferred to keep their findings to themselves as "secret processes" and thus did not publish any of their works for the benefit of the industry. This tradition of secrecy in magnet making is now happily broken down, as exemplified by the Kinnard-Goss paper.

F. A. Redding (Southern California Edison Company, Ltd., Los Angeles, Calif.): The contributions to watt-hour meter engineering knowledge by the authors of this paper in the past have been numerous and have exerted an important influence in this field of endeavor.

Their latest effort, "Braking Magnets for Watt-Hour Meters" is typical of the thorough manner with which they cover their selected subject.

Operating engineers are always interested when a complete change is suggested for one of the vital component parts of our watt-hour meters. While we all realize that progress necessitates changes, we are all concerned that such changes will not gain certain desirable characteristics at the sacrifice of some equally important properties of the unit which is to be replaced.

We have felt that the chrome steel magnet during the past decade has performed in an admirable manner, however with modern installations, certain shortcomings have presented themselves in this type of magnet, where the installation has been subjected to lightning surges or heavy short circuits.

A review of the subject matter and data presented in the paper by Kinnard and Goss definitely gives comparative data, obtained from quite elaborate tests to indicate that Alnico II when properly treated and used for watt-hour meter damping has all the desirable characteristics of chrome steel and in addition, will resist demagnetization from fields caused by heavy direct currents and lightning surges.

The method and equipment used for measuring the permanency of breaking magnets, whereby the personal error was eliminated through the use of photoelectric control gives very definite accuracy of results.

These results indicate a high degree of permanency, following stabilization treatment by aging as outlined, which of course is fundamental and a paramount characteristic in material used for this purpose.

The effective control of temperature errors is shown as even superior to that possible with chrome steel, this is most desirable because more and more of our meters are being mounted in the open without protection of any nature, and the temperature differential during any 24 hours often is a matter of wide range even in our more temperate areas.

The statement is made that "if desirable, this compensation may be increased to allow for errors in other parts of the meter." It is not clear to what other errors reference is made, but it would surely seem desirable to obtain increased accuracy whereever possible.

The data submitted from the varied tests conducted gives the operating engineer a feeling of confidence that the conclusions reached are well supported by technical proof and the Alnico II when used as a braking magnet for our watt-hour meters will prove very satisfactory.

I. F. Kinnard and J. H. Goss: Mr. Redding raises the question regarding just what is meant by adjusting the temperature compensation for the magnet to take into account other errors in the meter. As an example, there is a slight temperature change in permeability of the silicon steel of the electromagnetic driving element of the watt-hour meter and this affects the torque of the meter and is a class I error. This change is small but by adjusting the magnet compensation this error together with several other small errors may be corrected. This gives better over-all performance than if the magnet were compensated independently of the watt-hour meter. For a more complete discussion of this subject, see "Temperature Errors in Induction Watt-Hour Meters", I. F. Kinnard and H. T. Faus, AIEE TRANSACTIONS, volume 44, 1925.

Mr. Redding expresses the interest of operating engineers in the performance of such an important part of the watt-hour meter as the braking magnet. It was the belief of the authors that this interest existed and it was to fulfill this need that the paper was prepared.

G. J. Wey and V. S. Thomander state in their discussion that they have found that the methods of applying the demagnetizing surge have a marked effect on the ability of the magnet to resist the surge.

While they have not given sufficient data or detail to allow an evaluation of their method we would like to point out that in making surge investigations of this type the capacity of the surge generators must be kept constantly in mind. If the path of the conductor carrying the surge current is changed to increase its impedance, the shape of the wave may be changed. It has been pointed out that the demagnetizing effect depends both on the magnitude of the surge current and on the wave shape.

While it is one thing to set up testing methods that give easily repeatable results and minimum demagnetizing effect on a given design of braking magnet, it must be kept in mind that the testing of a specific braking magnet must be done under equivalent service conditions if the evaluation is to be valid.

All of the original work done by the authors on the surge demagnetization of magnets was carried out on General Electric chromium steel watt-hour meter braking magnets. The work was then repeated using bar magnets to obtain the data for this paper. The authors reasoned that data on a specific commercial design of braking magnet, while invaluable in studying that design, had limited value as compared to fundamental data on a standard shape of magnet such as a bar magnet.

We wish further to reiterate that we feel the results on bar magnets are very valuable to the designer from a qualitative point of view. They cannot be interpreted quantitatively but good qualitative agreement was obtained between the tests made on chromium steel braking magnets and bar magnets.

As regards the effectiveness of the 0.002-inch thick copper plate on the bar samples and the 0.015-inch to 0.018-inch thickness used by Wey and Thomander, we must again emphasize, as pointed out in the paper, that the two are not comparable. If the plating thickness on the samples was further increased, further improvement would result whereas there is little or no improvement on a chromium steel magnet with unplated air-gap pole faces beyond 0.010 inch for surges up to 20,000 amperes.

It should also be pointed out that the comparison of copper plating on chromium steel and a high coercive force material is the most favorable for a single surge demagnetization. For multiple surges, the superiority of the high coercive force material is even greater.

A very practical consideration is that should service tests show that further improvement in surge resistance is desirable, an Alnico magnet could be shielded by copper plating to give a magnet with still greater surge resistance whereas the chromium steel magnet with its copper plate cannot be further improved. Performance under service conditions will be needed to find out if the degree of improvement is sufficient.

The authors appreciate Mr. MacGahan's comments and are pleased to have the additional bibliography in his discussion.

Fault Voltage Drop and Impedance at Short-Circuit Currents in Low-Voltage Circuits

Discussion of paper 40-148 by O. R. Schurig, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 479–87.

A. G. Darling (General Electric Company, Schenectady, N. Y.): The factual data presented by Mr. Schurig is considered a most important contribution to the design of low-voltage systems. The data was obtained as a result of considerable dissatisfaction with arbitrary methods having little or no scientific background. Some disastrous failures have occurred at infrequent intervals to equipment thought to be adequate as determined by rule-of-thumb predicated fault currents. The tests reported by Mr. Schurig show that heavy short-circuit currents can occur in typical modern constructions of low-voltage equipment.

Not a little thought and time were expended in the selection of the equipment to be tested for impedance and arc drop in order that it be representative of equipment in ordinary use without repeating reliable previous investigations. Obviously, not all types of construction could be investigated, nor all types of faults. The majority of typical cases are believed now to have been covered. Certain experiments by other investigators covered a portion of the field but left the impression that severe faults are unlikely. Quite contrary to these erroneous conclusions, Mr. Schurig's data show not only that maximum values of current can be obtained in actual cases but also show that, given the correct constants of the circuit, the expected currents can be calculated mathematically and identify the circumstances under which currents are obtained.

Having available these new and extremely important facts, no undue chances need now be taken in the specification of adequate equipment, nor should there be any serious discrepancy between the results obtained by independent investigators.

As a result of the investigations reported by Mr. Schurig, the general theorem of short-circuit calculations has again been proved to hold true for low-voltage circuits; i.e., the magnitude of short-circuit current is equal to the voltage divided by the impedance. No claim is made that this is a novel or new phenomenon because it has been one which has been known for a long time. The tests merely show that if one wishes to discard guesswork he can be fairly accurate in the calculation of short-circuit currents by using the proper values of impedance. One of the chief reasons for conjectures has been the lack of a fairly accurate description of the circuit, together with a lack of readily available impedance data. Some of the important missing information has been supplied by Mr. Schurig.

Investigation of short-circuit intensities in low-voltage systems did not receive the attention it merits until the past few years when the growth of low-voltage systems in industrial plants and in city lighting voltage distribution brought this subject to the foreground. It is only necessary to realize that $^1/_{25}$ of the impedance of a 2,200-volt system will limit the current in a 440-volt system to the same number of amperes as will occur in the 2,200-volt system in order to appreciate that impedances of low order normally neglected in higher voltage circuits, have a material effect on currents in low-voltage circuits.

Short-circuit currents can be classified into at least four groups of current intensity. In analyzing the possibilities of short-circuit currents, it is well to keep these four groups in mind.

1. The bolted short circuit of minimum contact resistance will produce the highest short-circuit current.
2. An arc fault in a closely congested, enclosed area produces the next highest amount of short-circuit current.
3. An arc fault in assemblies not as closely congested and open to the atmosphere produces the third classification of currents.
4. Arc faults produced by foreign objects of such weight and mechanical resistance to movement as may be readily thrown off from the circuit give the lowest values of short-circuit current and the most rapid current-limiting effect.

Conjectures as to the intensities of short-circuit currents can be based somewhat on the law of probabilities, and with this conclusion there appears to be no serious divergence of opinion. For every source of power there are a number (n) opportunities for failures between source and secondary bus. An additional number (L) chances occur between the secondary bus and the ultimate use of power. The result is that, for one possibility of trouble at the source, there are $L \times n$ chances of trouble in the distribution system. As the impedance increases from source to the point of short circuit, the current decreases. Consequently, in point of number, most fault currents are low compared to the maximum possible currents. This conclusion should, however, not be amplified to the extent that, since the greatest number of faults are of low order of current, there is no need to provide against the maximum fault current. Further, the conclusion should not tend to minimize the importance of adequately protecting against a fault at the point of maximum current as a power failure at that point may cause outages to all loads, whereas a failure at a point of power usage is not likely to affect more than that one usage for a long period of time.

The question then naturally arises as to whether protection should be installed at all places in the system which is adequate against the maximum faults at those locations. Tactics in the design of the entire system can be used to justify the cost of insurance to service. If there is but one line of defense, that line should hold against all expected assaults. If on the other hand there are two lines of defense, each subject to the same intensity of assault but one line backing up the other, the importance of maintaining service through all parts of the outer line should be reviewed before deciding to have maximum required strength in both lines. If a weaker outer line is used, the amount of destruction that can take place is a factor not to be overlooked. Equipment that will not, upon failure, spread damage beyond itself is much more safe than a type that will affect its neighbors. For low-voltage circuits, air-insulated, metal-enclosed circuit-interrupting devices are available and should give a minimum of contingent damage. The ultimate user must take into account the chances for failures of circuit-interrupting devices in comparison with the chances of obtaining short-circuit currents in excess of their rated interrupting ability and arrive at a cost of insurance which he can justify in his business.

Certain types of interrupting devices can be used in series and obtain that degree of co-ordination and clearing time which insures relief from a failure in the outer one. This can be done by adjusting the tripping current of the inner or first defense device at or somewhat below the expected failure current of the outer or second defense line. In this way there is obtained a clearing of the failure before it has a chance to spread beyond its point of initiation.

The data given by Mr. Schurig constitutes a material addition to the factors known to govern short-circuit currents. Heretofore, arcs in general were presumed to materially limit short-circuit current and possibly act to interrupt the circuit before devices could act to do so. In the light of the new data, one must consider the type of construction and insulation used and gauge the results accordingly. In particular, guesswork and rules of thumb should definitely be put aside for the more accurate and safer method of including in the calculation the impedances known to exist in the circuit.

The Application of Ignitrons to Resistance-Welding Control

Discussion of paper 40-146 by M. E. Bivens, presented at the AIEE Middle Eastern District meeting, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 471–8.

J. H. Hutchings (General Electric Company, Schenectady, N. Y.): Recent developments indicate that ignitrons are destined to continue to make important contributions in the resistance-welding field.

These same tubes are now being used with magnetic energy storage welders to furnish the high direct current which flows in the welding transformer primary during the charging period. Their well-known qualities of small size, high current capacity, and reliable operation have made their application attractive. Capacity energy storage welding installations use these tubes to trigger the energy stored in the condenser bank into the welding transformer. Another ignitron connected across the welding transformer prevents current oscillation.

Ratings of ignitron tubes for standard a-c resistance welding are ably covered in this paper. However, the economies which follow conservative application of ignitrons within their ratings cannot be overemphasized. These tubes depend on maintenance of good vacuum for their control properties. Inadequate water cooling or overload, even for very short periods, can do irreparable damage and short life can result. Conversely, if proper operating conditions are maintained, extremely long life can easily be obtained. This is proved by the fact that many of the first tubes installed four and five years ago throughout the country are still functioning perfectly.

Proper application of tubes reduces the need for maintenance to a practical minimum. The maintenance problem can be further simplified because ignitron tubes are sturdy, simple devices which are easily tested for most important characteristics. Quite a satisfactory job can be done in checking the ignitron tubes in a welding control panel with only an ohmmeter for measuring ignitor resistance and a hand spark coil for checking vacuum. Tube manufacturers supply complete instructions for performing these simple tests. An example is *GEI*-13627, a two-page publication supplied by the General Electric Company.

As users become more and more familiar with the characteristics and possibilities of ignitron tubes, misuse will tend to disappear and the great economies which tubes provide will become even more apparent.

Two New Methods of Accelerating Electric Motors Automatically

Discussion and author's closure of paper 40-142 by John D. Leitch, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 487–93.

B. W. Jones (General Electric Company, Schenectady, N. Y.): The author reviews the several methods that have been used in the past for accelerating d-c and a-c motors and refers to them as:

1. Counter electromotive force method
2. Series lock-out method
3. Constant-time method
4. Time-current method

He points out the disadvantage of the several methods and says of "constant-time": "One decided disadvantage of the 'constant-time' method becomes apparent when very heavy loads are encountered, in that the acceleration contactors will close before the motor attains any appreciable speed and the resulting excessive currents may cause considerable damage."

I wish to call attention to some tests that were made a few years ago to show just what does happen under this condition. Some records can be found in the April 1925 issue of the *General Electric Review* and oscillographic records reproduced here show what takes place when a series motor is reversed from full speed in one direction and brought up to full speed in the opposite direction under three degrees of load; namely, no load, rated load, and twice rated load. The type of control used is that which the author calls the constant-time method. The sys-

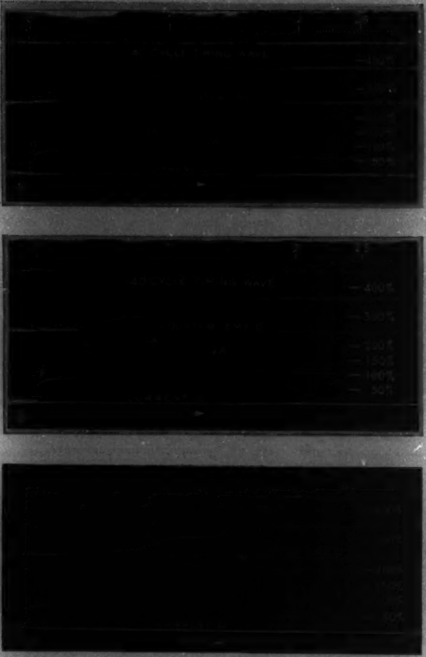

Figure 1. Effects of reversing a series motor under zero load (A), full load (B), and 200 per cent load (C)

tem employed for these records consists of a counter electromotive force effect for controlling the plugging contactor for stopping the motor but the two accelerating contactors were controlled by two relays which interposed a fixed time preceding the closing of each of the two accelerating contactors. These records show that the resulting accelerating current peaks labeled *F*, *P*, 1*A*, and 2*A* were exactly what should have resulted. They increased as the load increased and decreased as the load decreased, but at no time were the current peaks more than proportional to the load being accelerated.

The author states that the constant-time system is very generally used and this record clearly illustrates why the industry is favorable toward this principle. A second reason why constant-time is popular is that it is simple.

It is on the assumption that the current peaks become dangerously excessive that the author bases the need for the "time-current method," but the above records do not substantiate that there is any such need.

John D. Leitch: Mr. Jones seems to have misunderstood my statement in the introduction under the heading "Constant-Time Method." Actually the comparison is being made with the two methods which precede it. The four methods described in the introduction are examples of two entirely different principles—one in which the acceleration contactors close when the motor reaches a definite speed and the other in which the contactors close after a time interval independent of motor speed. The "counter electromotive force" and "series lock-out" methods are applications of the former of these two principles while the "constant-time" and "time-current" methods are applications of the latter.

Mr. Jones' criticism is directed against the "time-current" method in comparison with the "constant-time" method and he has submitted oscillograms to prove or disprove his statements. The oscillograms show the motor current and counter electromotive force for 50 per cent, 100 per cent, and 200 per cent full load on the motor. The peak values of the current at 100 per cent load are quite uniform indicating a good adjustment of the constant-time intervals. No advantage for time-current acceleration can be shown at 100 per cent full load since that is the condition for which the relays are adjusted to give uniform peaks just as they have been for the case shown on the oscillogram.

At 50 per cent full load, the 1*A* and 2*A* current peaks are successively less than that at which the *P* contactor closed whereas with time-current acceleration in which the time interval is automatically decreased with decrease in load, the 1*A* and 2*A* contactors would close earlier and give more uniform peaks and more rapid acceleration of the motor.

At 200 per cent full load, the 1*A* contactor closes before the motor has gained any appreciable speed as shown by the counter electromotive force trace on the oscillogram. With time-current acceleration, more time would be provided automatically before 1*A* closes and the peak current would be lower. Similarly with the 2*A* contactor. Thus, obviously, there is no reason why the peak currents need be proportional to the load if some means is provided for increasing the time intervals with increase in load.

In other words, time-current acceleration provides slower acceleration on heavy loads and more rapid acceleration on light loads with greater protection for the motor, which, after all, is the purpose of any acceleration method. The two new methods described in the paper are also examples of the two fundamental schemes of acceleration. The frequency acceleration relays described in part 1 close at definite motor speeds while, in part 2, "time-limit" acceleration both "constant-time" and "time-current" is provided with a neon tube timing circuit.

The Effect of Overexciting Transformers on System Voltage Wave Shapes and Power Factor

Discussion of paper 40-137 by J. W. Butler and E. B. Pope, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 49–53.

Eric T. B. Gross (College of the City of New York, N. Y.): About ten years ago, a few papers were published in Germany concerning higher harmonics due to transformer saturation[1]; but these papers were chiefly of academic interest, as serious difficulties had never arisen because of higher harmonics. Furthermore, investigations on higher harmonics in various transmission and distribution systems of different voltages and character had shown that, in general, higher harmonics decreased with increasing load; thus, it can be understood easily why the effect of higher harmonics due to transformer saturation under "no load" conditions of the network is limited and unimportant.

The problem got a new impulse, however, when war preparations in Germany made it advisable to reduce the demand on iron. In this country, T. C. Lennox had found[2] that the fifth and seventh harmonics in the magnetizing currents of star and meshed connected three-phase transformers are of opposite phase and equalize each other if used in the same or neighboring stations. On basis of this fact, J. Biermanns (Berlin) and R. Willheim (Newcastle-upon-Tyne) suggested[3] the connection of the magnetic flux of one transformer in star and mesh, thus suppressing higher harmonics in the external magnetizing current of the transformer and making it nearly sinusoidal. To adapt the normal construction of transformers to this principle, it is only necessary to split the yokes and to use additional low voltage windings on yokes and cores; these additional windings are to be designed for the magnetizing currents of the higher harmonics and need only to be relatively small. Higher saturation is thus permitted, as far as the harmonics are concerned, so that iron can be saved. However, due to higher saturation the losses are increased and the transformer less efficient than otherwise. Under the present economic conditions in Germany, this is apparently less important than the reduction of the iron volume. It seemed to me that this solution of the problem was of general interest as it might be used with advantage in the construction of transformers with usual flux density and economically designed losses.

Some Insulator Designs Require Special Features to Insure Radio Quietness

Discussion and author's closure of paper 40-144 by Charles J. Miller, Jr., presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 62–6.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): While the author deals specifically with line and station porcelain insulators, certain principles on the radio-noise problem which he enumerates have been recognized and established quite generally and therefore they apply equally to other high-voltage apparatus and equipment. For instance, I have reference to the methods of measurement which through the efforts of many (in particular the pioneering work of Aggers and Pakala—*Electric Journal*, December 1933) have been standardized along practical and fundamental lines ("Methods of Measuring Radio Noise"—EEI Publication No. G9—NEMA Publication No. 107—RMA Engineering Bulletin No. 32). Naturally one of the benefits accruing from this systematic standardization process is that a wide range of experience and comparable test data have been accumulated in the past five years to the extent that test codes covering most apparatus and equipment practically are available at this stage.

As these test data became available and experience crystallized, an important principle became apparent. It became clear that the permissible radio-noise voltage levels for high-voltage apparatus and equipment fundamentally should follow upward steps graduated with increase in voltage rating and for two reasons in particular. In the first place, possible sources of increasingly high-radio disturbance inherently are removed from the radio receiver a greater amount (coupling factor) for the higher voltage than for the lower voltage circuits. Second, it is recognized that the problem of designing apparatus for a minimum radio noise is both technical and economical—the higher the voltage class of the apparatus the higher the permissible radio noise-influence voltage level. This does not mean that the same levels are necessary or justified for all apparatus. In fact there are good reasons why higher levels are permissible for station than for line apparatus—a point that the author also has touched upon.

Another consideration of importance has been the test voltage at which the radio noise-influence voltage shall be measured. There has been a good deal of confusion on this point for the voltage at which apparatus may operate is not always defined. In the case of transformer or other potential apparatus, the problem is simplified in that the induced voltage applied to the winding shall not exceed ten per cent above the winding voltage. The desirable test voltage is at 110 per cent of the maximum rated line-to-neutral voltage. For apparatus for which induced tests cannot be made, such as series transformers, circuit breakers, insulators, etc., a test voltage based on 110 per cent of the insulation-class voltage divided by the square root of three appears proper and desirable.

There has also been some confusion as to whether the per cent overvoltage in testing apparatus for the radio noise-influence voltage should be 5, 10, or 15 per cent or some other figure. It now appears that ten per cent is an adequate amount, and a logical figure for this will work toward uniformity in that it makes it possible to test all types of apparatus, either induction or series, on the same percentage overvoltage basis. This test voltage should provide adequate assurance that the radio-noise level of the apparatus is not exceeded even for a voltage somewhat above the normal rating and it also should give the further assurance that the radio-noise characteristic exhibited by the apparatus is of a stable character within the possible operating range.

Charles J. Miller, Jr.: The comments by Mr. Bellaschi are very interesting as they indicate that electrical manufacturers in general desire a standard means of measuring radio noise-influence voltages in the factory so that they may manufacture devices which will not cause radio interference when placed in service.

The instrument and circuits devised by the joint co-ordination committee cover all types and classes of electrical equipment from 110-volt motors to the highest voltage insulators. The circuit for high-voltage devices is but one of several circuits devised, and the testing of insulators is but one application of the high-voltage circuit, as Mr. Bellaschi has pointed out in his comments. However, having an instrument and a coupling circuit, it still remains for each industry to establish its own test code, consisting of test voltages and permissible microvolt levels. Since permissible microvolt levels may vary with the type of device and its application, it is probable that no general levels can be established which apply to all types of equipment.

It is the desire of progressive electrical manufacturers to produce radio-free devices and the advent of a standard method for measuring radio interference in the factory has been welcomed with open arms by a majority of the electrical industry.

A New Current-Limiting Fuse

Discussion and authors' closure of paper 40-158 by H. L. Rawlins, A. P. Strom, and H. W. Graybill, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 77–80.

E. A. Williams, Jr. (General Electric Company, Philadelphia, Pa.): The introduction of the paper, "A New Current-Limiting Fuse," seems to imply that the reduction of electromagnetic forces, by a substantial limitation of peak short-circuit current, is only of incidental interest. There may be some logical reasons for this implication when applied to the fuse described by the authors as it is apparently limited to application with potential transformers and small control transformers. However, the real value of "limiting" the short-circuit current has been spectacularly demonstrated by testing 2,500-volt oil immersed contactors in series with conventional fuses and again in series with current-limiting fuses. With an available short-circuit current of 14,000 amperes, the conventional fuse interrupted the 2,500-volt circuit in one-half cycle, but the tank of the contactor ripped open. In contrast, the 200-ampere current-limiting fuse interrupted a 2,500-volt circuit having well over 150,000 kva available with absolutely no damage to the contactor.

Since the authors found it desirable to construct the "new current-limiting fuse" principally from fiber, they must necessarily take precautions to protect this organic material from excessively high temperature. The silver wire, wound directly on the fiber, has a melting temperature of approximately 960 degrees centigrade, and this temperature will destroy fiber in a very short time. This fact has been recognized in the design, and the main or "clean up" fuse element has been "calibrated to melt at a lower current than the auxiliary fuse element." With this limitation in mind, it is rather difficult to see how this main element "can be designed to give any desired time-current characteristics."

The theory and calculations presented by the authors appear to be based on certain assumptions which apply only in a very limited range of short-circuit currents and fuse sizes. The current rise through a fuse of low-current rating does not follow the law, $i = 377 I_m t$ because the resistance of the fuse varies with temperature and is usually high relative to the impedance of the remainder of the circuit. For this reason, during the melting period, the low-current fuse sees a continuously decreasing available short-circuit current which is appreciably lower than that actually available in the circuit in the absence of the fuse.

The current rise through a fuse of high-current rating also fails to follow the law, $i=377I_mt$, but for an entirely different reason. Such a fuse requires so long to melt that even a relatively high short-circuit current will deviate sufficiently from a linear rise to invalidate the assumption. The inaccuracy of the authors' assumptions are well illustrated by reference to the family of current-limiting curves given in figure 1 of this discussion. These curves are based on the results of actual short-circuit tests and show the instantaneous current at the instant the fuse melts, when subjected to a symmetrical current, as a function of the available asymmetrical current.

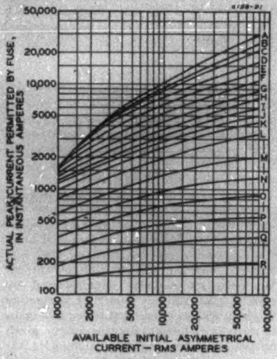

Figure 1.

A—300/200*N* amperes
B—250/150*N* amperes
C—200/125*N* amperes
D—150/100*N* amperes
E—125/80*N* amperes
F—100/65*N* amperes
G—80/50*N* amperes
H—60/40*N* amperes
I—50/30*N* amperes
J—40/25*N* amperes
K—30/20*N* amperes
L—25/15*N* amperes
M—15/10*N* amperes
N—10/7*N* amperes
O—7/5*N* amperes
P—3/3*N* amperes
O—2/2*N* amperes
R—1/1*N* ampere and lower

Note that the 1/1*N* ampere fuse will pass a peak current of 180 instantaneous amperes with 10,000 rms amperes available and that this peak current increases to only 198 instantaneous amperes with 80,000 rms amperes available. According to the authors' predictions, the peak current should have increased to 360 instantaneous amperes. At the other extreme, we find that the peak current permitted by the 300/200*N* ampere fuse increases from 10,000 instantaneous amperes with 10,000 rms amperes available to 29,500 instantaneous amperes with 80,000 rms amperes available whereas the authors' theory would predict this latter peak current to be only 20,000 instantaneous amperes. However, it is appreciated that the authors are dealing with fuses of low-current ratings and that for these particular fuses, the errors in the assumptions are on the safe side.

The statement that the commercial development of the current-limiting fuse for use in this country was abandoned is evidently not intended by the authors to apply generally since this development has been carried forward with very practical results.

A. D. Fishel (A. D. Fishel Company, Cleveland, Ohio): The authors of this paper are to be complimented on their novel approach to designs of current-limiting fuses.

In the calculations under "Theory and Calculations" it is believed that the energy required to supply the latent heat of fusion, is a factor which should also be given consideration in the computation of the maximum value of initial current rush, as a function of fuse wire mass and the prospective fault current.

An ingenious means is employed to suppress abnormal voltages caused by the rapid suppression of current during a short circuit. The voltage surge which occurs during the operation of a current-limiting fuse, is a function of the current magnitude reached prior to the instigation of the current-suppressing process and of the speed with which the current suppression takes place. This means that the problem becomes more difficult as the current-carrying ability of the fuse or the time-lag characteristics of the current-responsive element, are increased.

During the past four years, Schweitzer and Conrad, Inc., have manufactured current-limiting fuses for installations with capacitors and have also a considerable number applied in potential transformer installations on industrial systems, as well as in other specific applications where these fuses are installed to obtain operating experience.

While operating results have been satisfactory, it is felt that the current-limiting fuse is not a substitute for the resistor and fuse combinations, which have found wide application in the past. This is due to these facts: the flashover value of a current-limiting fuse following low-current operation, is less than that of the conventional fuse; the current-limiting type does not possess the same flexibility in time-current characteristics; voltage surges occur during the operation of a current-limiting fuse which do not occur when the conventional fuse and resistor combinations are applied.

The authors' design embodies a general arrangement and function of elements similar to those which Schweitzer and Conrad applied in current-limiting fuses, that is, the spring-actuated, current-responsive element performs the dual function of protecting the current-limiting element during low current, to clear the circuit and obtain a suitable gap between the severed ends. In the authors' design, the clean-up element performs the added function of preventing leakage through the current-limiting portion of the fuse, after operation on heavy prospective fault currents. In the Schweitzer and Conrad design, this duty is not required, because during short circuit, the current-limiting section of the fuse changes from low-resistance conductor to an insulating oxide.

It is the opinion that current-limiting fuses will distinctly improve fuse installations which now contain powder-filled fuse assemblies of insufficient interrupting capacity, and where the available space does not permit the conversion to other modern types of protective equipment. It is felt that for installations in which absolute dependability is required, the current-limiting fuse is not the operating equivalent of either fuse and resistor combinations or modern power fuses.

H. L. Rawlins, A. P. Strom, H. W. Graybill: The discussions presented emphasize both the scope of application and the limitations of the current-limiting fuse. Mr. Fishel points out that the current-limiting fuse has the disadvantage of producing voltage surges during operation. This has been one of the major limitations of current-limiting fuses, and was one of the major factors involved in the design of the new fuse. As stressed in the paper, the construction and characteristics of the fuse are such that overvoltages are definitely limited.

It is further stated that current-limiting fuses have low flashover values after low current operations. To assure high flashover values in this new fuse, the main element is spring operated. A positive gap is, therefore, introduced, even when the fuse operates on very low currents.

Mr. Fishel points out that current-limiting fuses do not have the same desirable time-current characteristics as conventional fuses, and Mr. Williams wonders how suitable time-current characteristics can be achieved in these fuses when the main element must blow before the parallel current-limiting element.

In the new fuse, the main element is essentially a conventional fuse. In order to maintain the parallel current-limiting element—operating in series with the main element before fusing—at a low temperature, it is essential that the minimum or long-time melting current of the main element be only a small fraction of that of the parallel current-limiting element. This allows a wide range in the short-time melting current of the main fuse element without exceeding safe temperatures in the current-limiting element. This range is sufficient to cover any desired time-current characteristics.

The question is raised concerning the effect of the latent heat of fusion on the fusing time. With the current increasing at a constant rate as occurs in this fuse, at the time of fusion, the increase in the calculated fusing time of a silver wire is only five per cent or six per cent when the latent heat of fusion is included. Photographic and experimental evidence proves that only a small part of the heat of fusion has been supplied when arcing begins. These two factors show that the effect of the latent heat of fusion can safely be neglected in calculating the current at the time arcing starts.

As explained in our paper, the equations give the maximum possible value of fusing current as a function of the symmetrical available short-circuit current. Under conditions that give the maximum possible fusing current, symmetrical currents are essentially linear with time up to the fusing point, and follow the law, $i = 377 I_m t$. Practically all currents that are large enough so that the current-limiting function of the fuse comes into play lie in this range.

It should be emphasized that even on asymmetrical currents, fusing currents will never rise higher than calculated by these equations since the average slope of the current curve is then always less than $377 I_m$. On fusing currents that depart from linear due to fusing times longer than about one-sixth half cycle, the actual fusing currents must always be smaller than calculated by the equation. Likewise, on short circuits in which the current is limited by the resistance of the fuse element itself, the maximum fusing current will obviously be smaller than the calculated value.

In deriving the equation, it was assumed that the fuse wire itself, before melting, does not limit the current. This is the worst condition that can be imposed on a current-limiting fuse, and hence always gives conservative results. The departure from the results computed by the equation will depend on the relative increase in impedance introduced by adding the fuse to the circuit. Fuses having low-ampere ratings have high impedance and, therefore, depart farther from calculated results than larger ampere rating fuses. Fuses of the same ampere ratings depart more from the calculated values on large short circuits than on smaller short circuits, and more on low-voltage circuits than on high-voltage circuits.

Curves such as given in Mr. Williams' discussion can, therefore, apply only for one particular design of fuse operated at one particular voltage. Had these data been obtained at, say, ten times the voltage, these curves would undoubtedly approach the limiting conditions as expressed by our equations.

In the second example given in Mr. Williams' discussion where the instantaneous current reaches 10,000 amperes on a 10,000-ampere asymmetric circuit, the fusing current is actually higher than the symmetrical peak. In this case, no current limiting occurs on symmetrical currents, and only slight limiting on full asymmetrical currents. The observed fusing current must, therefore, be lower than calculated by our equation, and cannot be compared to the 80,000-ampere case.

However, if we avoid currents so low that fusing requires most of the half cycle, or so high that the fuse element comprises an appreciable part of the circuit impedance, the data presented by Mr. Williams shows that fusing currents double when the available current increases by eight times, as predicted by the equation. This is shown in the accompanying tabulation of data from Mr. Williams' curves (table I).

Table I

Fuse Rating	Fusing Currents (Amperes) 1,000 Available	8,000 Available	2,000	16,000	5,000	40,000	Ratio of Fusing Currents
3/3 *N*	253	445					1.76
7/5 *N*	350	670					1.92
10/7 *N*	455	905					1.99
15/10 *N*			780	1,530			1.96
25/15 *N*			1,080	2,130			1.97
30/20 *N*					1,900	3,750	1.98
40/25 *N*					2,200	4,300	1.95
50/30 *N*					2,450	4,850	1.98

The equations given in this paper are particularly useful in understanding the operation of these fuses, and in making preliminary design calculations.

This new fuse has characteristics that make it particularly desirable for the protection of potential and small power transformers. The fuse shown in the paper was for such service. However, the design is particularly applicable for higher current ratings where the voltage-limiting characteristic becomes of utmost importance.

Higher voltage surges will occur in a current-limiting fuse where the resistance of the element does not limit the current than where the resistance of the element limits the current. Therefore, the higher ratings of fuses tend to produce higher voltages during operation.

Standard power fuses have been used for years to protect low-rated equipment. Except in the case of extremely low-rated equipment, as mentioned by Mr. Williams, the equipment has been adequately protected. With current-limiting fuses operating in series, the voltages produced during operation add. In the case of conventional fuses, the voltages do not add. The field for current-limiting fuses, therefore, will probably be limited to those applications where their special characteristics are required.

The "Black Band" Method of Commutation Observation

Discussion and authors' closure of paper 40-138 by T. W. Schroeder and J. C. Aydelott, presented at the AIEE Middle Eastern District meeting, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 446–51.

T. M. Linville (General Electric Company, Schenectady, N. Y.): This paper ably describes a valuable method. However, it does not point out certain implications of the data presented which are important.

First, a viewpoint of "differential reactance voltage" is frequently used which differs from the concept explained under "Differential Reactance Voltage" (part 4). A coil short-circuited by the brushes (that is, undergoing commutation) is considered to have three voltages, a "reactance voltage" (due to self and mutual induction), a generated voltage (due to the commutating field), and a brush voltage. In an ideal machine, when the reactance voltage and generated voltage are equal there is no brush voltage (for the coil) and no differential voltage. However, if by misadjustment the generated voltage is too big or too little the difference between it and the ideal reactance voltage will not appear as a brush voltage entirely, as suggested by the paper, but will be absorbed in a change in the reactance voltage occurring simultaneously with the appearance of brush voltage.

In a practical machine it is never considered possible to balance the two voltages bringing the brush voltage to zero because the wave shapes cannot be made the same. I believe this difference in wave shape or in instantaneous values is the commonly accepted definition of "differential reactance voltage." This difference can and does exist even when the machine is correctly adjusted in accordance with the black band. It is partly the cause of black-band closure and is one source of the evil when no black band can be obtained for any commutating field adjustment.

It is interesting to note that the majority of the black bands illustrated are substantially uniform in width independent of load. This would indicate that either the reactance and generated voltages do nearly balance each other at all instants, or else the brush voltage is able to take care of this difference without affecting the amount of buck and boost that can be taken care of.

These black bands suggest that there is no limit to permissable reactance voltage since this voltage increases with load while the bands maintain uniform width without tendency to close. In their terms commutation is no better at half load for example than at full load. However, on variable-speed motors the bands invariably are narrower at the top speed, where for equal loading the reactance voltage is higher in proportion to the speed.

The black-band method is not an inflexible measure of commutation performance. For example, a machine having very little commutating pole air gap and little nonmagnetic shims will require less commutating pole ampere-turns to establish the commutating field than a similar machine having twice as much total commutating pole air gap. In the second case the buck and boost applied to the commutating field will be about twice that of the first case for the same effect on commutation. In other words the width of the black band in terms of amperes and in terms of per cent of rated current will be twice as great. And yet the commutation will be no different in the two cases and the margin for changes in the commutator film, brush riding conditions, etc., will be alike. However, the commutating pole shims or the shunted amperes will not have to be adjusted so precisely in the second case.

Mention is made of the effect of commutating pole tip width on the commutation and in agreement with the paper d-c designers seek to determine the optimum width. In this connection figure 11 is interesting showing the effect when the brushes are shifted so that part of the main-pole flux joins the commutating field flux. Varying the main-pole flux from zero to full voltage has substantially no effect on the width of the black band, even though it is equivalent to extraordinary distortion of the commutating field flux. Apparently the distribution is not important in this case and the commutating coils transfer the generated voltage by induction. The paper suggests this in stating that the "trailing edge spark does not appear to be critical of tip width unless the rotation of the machine is such that the last conductor to commutate in a slot is a top conductor." It should be pointed out that many reversible motors commutate equally well in both directions of rotation, although the last conductor is a top one with one rotation and a bottom one when running oppositely.

It is believed that the table under "Black Band Width and Closure" must mean that the narrow black bands with 5,000 feet per minute commutator speed is caused by higher reactance voltage in proportion to the speed and not by the commutator speed itself.

Black-band tests are sometimes made after a fashion without a source of buck and boost power. This is done by replacing all nonmagnetic shims with steel to produce a strong commutating field. The strength of the field may then be varied by shunting current to determine the range of adjustment and the amount of shims to be used or current to be shunted to center the band.

T. W. Schroeder and **J. C. Aydelott:** We appreciate the interest which Mr. Linville has shown in commenting on our paper. His remarks are in large part a valuable addition to the material in the paper. Toward the end of his discussion, however, Mr. Linville makes the statement that "many reversible motors commutate equally well in both directions of rotation." We can agree with Mr. Linville if we can interpret this statement to mean that many reversible motors commutate successfully in both directions of rotation. The fact, then, that one rotation was better than the other would naturally not be observed and would be of no particular consequence, since the commutation in the poorer rotation was entirely acceptable. We wish to repeat, however, that many machines show a distinct difference in commutation in the two rotations. This is sometimes most evident before the final adjustment of commutating pole-face width is selected, and may be minimized if equalizing the commutation in the two rotations is one of the governing considerations in the choice of commutating pole-face width. As stated in the paper, we trace this difference in behavior in the two rotations to the fact that in one rotation the last conductor in the slot to be commutated is in the top polycoil in the slot, whereas in the other rotation, the last conductor to be commutated in the slot is in the bottom polycoil.

In his next paragraph, Mr. Linville comments upon the effect of commutator speed on the closure of "black bands." While we agree that increased reactance voltage proportional to increased speed does tend to cause a narrowing of the "black band" and eventual closure, we also believe that it is a matter of common observation that particularly in the high-speed range, commutator speed itself can be a cause of sparking. This is sometimes called mechanical sparking. Practically, this means that a designer must use lower values of reactance voltage to insure the successful operation of machines with high commutator speeds, as compared with the relatively high values of reactance voltage which can be operated successfully with low-speed designs.

A Comparison of the Relative Efficiency of the Schafer and Pole-Top Methods of Artificial Respiration

Discussion and authors' closure of paper 40-150 by W. B. Kouwenhoven, D. R. Hooker, and O. R. Langworthy, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 41–4.

H. B. Williams (nonmember; Columbia University, New York, N. Y.): It seems likely that in any case requiring resuscitation the chance that the effort will be successful diminishes in porportion to the time, perhaps more rapidly than a simple proportion. Mr. Oesterreich's work in the devising of the method of pole-top resuscitation has provided means for commencing this procedure with a minimum of delay. Dean Kouwenhoven and his associates have performed a most commendable service in showing its actual efficiency as a means of ventilating the lungs. I suspect that it does more than this.

Ventilation of the lungs would be futile if movement of blood did not carry the oxygen to the tissues and carbon dioxide away from them. There is good reason to believe that following release from a power line a shocked person will suffer a considerable fall in blood pressure. It seems likely that the pole-top method of resuscitation is also effective in promoting movement of blood. It was shown some years ago at the Physiological Laboratory of Columbia University that even in sheep with ventricular fibrillation it is possible by vigorous manual effort to maintain some circulation. The effect on circulation may be as important an element in the success of the new method in the field as is the promptness with which it can be applied.

This all being admitted, it must still be borne in mind that the pole top is a dangerous place. The position of the rescuer below the victim tends to lessen the danger to the former, though sometimes the accident may be due to electrification of parts of the structure other than the normal conductors and this may increase the danger to the rescuer. It not infrequently happens that the beginning of recovery is attended with convulsions. This was recognized by Mr. Oesterreich in his original communication. That this involves an element of danger is shown by a case brought to my attention last week. An injured lineman was being resuscitated, apparently with success. A convulsion occurred and his hand came in contact with a live wire so that he received a second shock from which it was impossible to resuscitate him. The danger to a rescuer under such circumstances is evident. Such an occurrence might have involved a fatal shock to the rescuer also. It may be possible to devise some simple means of confining the injured person's arms. I believe Mr. Oesterreich recommended removal of the spurs to prevent injury to the rescuer by convulsive movement of the legs.

While I am loath to deny to any injured person the benefit of any method which may offer a better chance of survival I think these considerations should be weighed and that crews should be trained to use judgment as to when the danger of attempting the pole-top method is too great. Any company which has not as yet used the method will do well to secure the services of someone who has had experience to assist in training its crews.

The above represents the personal views of the speaker only as the Resuscitation Review Board of the Edison Electric Institute has not yet formulated an opinion on this matter.

W. B. Kouwenhoven: Dr. Williams' discussion is most gratifying and we welcome his suggestions. This paper presents the report of the first stage of our investigation. The work is being continued. We are now studying the effect of the time elapsing between the shock and the starting of artificial respiration on the chances of recovery. In addition, we plan to determine the influence of artificial respiration upon the circulation of the blood.

The Use of Auxiliary Impedances in the Single-Phase Operation of Polyphase Induction Motors

Discussion of paper 40-139 by Raymond W. Ager, presented at the AIEE Middle Eastern District meeting, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 494–9.

Wayne J. Morrill: See discussion, page 669.

R. J. W. Koopman (University of Kansas, Lawrence, Kans.): Professor Ager has taken a problem and has made interesting analyses of many of its ramifications. A study of this paper should be valuable to students trying to gain an understanding of capacitor and split-phase motors.

An interesting point comes up on further consideration of the operation of the motor shown in figure 9 of the paper at less than 70.7 per cent power factor.

The accompanying figure is figure 9 redrawn for a power factor of less than 70 per cent. The dotted lines represent I_1 and I_2 when Z_2 is a resistance and Z_1 is a perfect condenser. The solid lines represent the currents when Z_2 is still a resistance, but disconnected from I_1, and connected in parallel with Z_1. It is clear from the figure that less condenser capacity is required in the latter case than in the former.

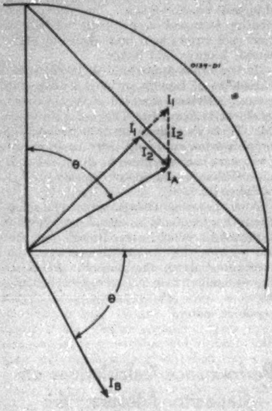

Figure 1

In other words, we have an instance where a leaky or imperfect condenser is superior to a perfect one.

The same connection could be used to give balanced motor voltages for the three-phase motor of figure 5 if it were operating below 50 per cent power factor.

P. L. Alger (General Electric Company, Schenectady, N. Y.): The thought developed by Professor Ager that single-phase capacitor motors should be designed for operation with nearly balanced currents, approaching polyphase conditions, is logical. Many engineers, including especially Biermanns in Germany, have proposed means to this end, but the narrow load range over which any particular set of impedance values gives approximate phase balance makes such balanced operation of only secondary importance.

Under present conditions capacitor motors are usually operated at speed as plain single-phase motors, and capacitors are only used in the running connections when unusually high starting torque per ampere is required. In these cases, the running capacitor is made just large enough to give the desired starting performance, and the resulting characteristics at full speed are accepted without further consideration.

Professor Ager has also mentioned the possibility of using double squirrel-cage rotors in capacitor motors as a means of obtaining better starting conditions and lower full-load slip. These benefits are secured if the motor is operated at a load close to the point of phase balance. However, the large increase in the resistance of a double squirrel cage for double frequency currents makes the extra losses due to the backward revolving field very large, cutting down the motor torque and raising its heating. For most practical motor applications this disadvantage has been found to more than offset the possible gain. For a particular application where the operating load is fixed and known in advance, however, a double squirrel-cage rotor in conjunction with a capacitor adjusted to give balanced operation should give very desirable characteristics.

Performance Calculations on Repulsion Motors

Discussion of paper 40-152 by P. H. Trickey, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9-11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 67-73.

Wayne J. Morrill: See discussion, page 669.

T. C. Lloyd (Robbins and Myers, Inc., Springfield, Ohio): Mr. Trickey's paper presents a useful extension of the West analysis, by a tabulation simplifying the calculation processes. It is true that such calculations are made at comparatively rare intervals but a much more common problem is that of the starting performance. Inherent with this are the effects of saturation and brush drop. On the latter point Mr. Trickey has indicated a process for obtaining r_3 with no mention of comparative accuracy for starting torque calculations against tests, nor the upsetting effects of brush pressure and temperature.

Mr. Trickey has indicated in the discussion that the accuracy to be expected is not greater than about 25 per cent in calculating starting torque and amperes. This is about the range of accuracy which we have obtained in our own experience. Yet the fault is not due so much to the analysis as to the inherent nature of the problem. Calculations made with older methods of analysis neglecting the effect of r_3 have been off as high as 300 per cent when compared to tests.

Because of this lack of agreement between tests and calculation I question the practicality of following through the involved calculations for starting torque and current. Thinking that some approximations might be justified the following analyses were made.

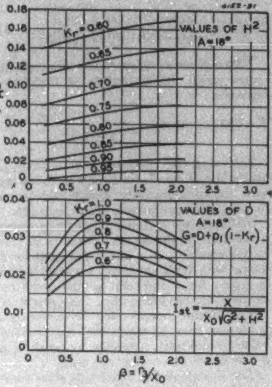

Figure 1

The final torque equation eliminates the effect of r_3 but in light of Mr. Trickey's curves of figure 5 there is some question as to whether such neglect is justified. But by using ratios of constants, curves could be drawn as shown, greatly simplifying the work.

At standstill, West's equation for current becomes:

$$V=I_1\left[jX_m+X_m{}^2\left(\frac{\cos^2 A}{r_3+jX_0}+\frac{\sin^2 A}{r_3+jX_0''}\right)+r_1+jX_1\right] \quad (1)$$

Table I. Calculated and Test Data

Horsepower	3	2	1½	1	¾
Poles	4	4	4	4	4
Com. bars	79	79		79	79
Cond. (primary)	432	576	616	792	1,008

H	0.008	0.014	0.011	0.011	0.012
I_1 (calc.)	55.1	30.5	28.2	20.1	15.25
I_1 (test)	61	32.0	32.2	19.0	14
T syn. watts	12,000	7,650	5,350	4,550	3,490
T oz-ft (calc.)	750	479	335	285	217.5
T oz-ft (test)	680	472	370	270	201

This reduces to:

$$I_1=\frac{V}{X_0\sqrt{G^2+H^2}} \qquad (2)$$

Where G and H are derived from curves as shown, plotted for a definite brush shift (18 degrees).

The starting torque equation is:

$$T=I_1^2X_m^2\frac{(r_3^2-r_2^2)X_0 \sin A \cos A}{(r_2r_3-X_0^2)^2+(r_2+r_3)^2X_0^2} \qquad (3)$$

This reduces as shown below by dropping terms which appear to be of little significance:

$$T=I_1^2K_rX_0 \sin A \cos A \frac{\beta^2}{\beta^2+1} \qquad (4)$$

Following this procedure one obtains I_1 by the use of curves for G and H, following with the comparatively simple calculation for torque in synchronous watts from (4).

Although one hesitates to confess to such unscientific methods, one advantage of this torque equation rests in the fact that for a motor with tests available, equation 4 can be solved for β and then for the brush resistance to be used with that grade of brush. Future designs using the same brush grade can then be made with the verified value of resistance, corrected by brush area if new brush dimensions are used.

The accompanying tabulation gives comparative calculated and test results for a line of motors from three-fourths to three horsepower. Although the accuracy is fair, such consistent results are not to be expected, and we are not using the method as a standard part of design procedure.

It is my belief that the main source of error, outside of unpredictable temperature effects, is the saturation of the magnetic circuit. We were recently called upon to design a repulsion-start induction motor crowded down to about half of its usual volume. Fairly satisfactory running performance was obtained, but whereas we had every reason to expect a good starting torque by comparison with previous designs, the starting torque per starting ampere was only half of that obtained in the more generously proportioned motors. No design changes could be found to improve this condition, which could be attributed only to the high degree of saturation of the magnetic circuit. Doubtless this exists to a lesser extent as an unpredictable source or error in all of these calculations.

Our experience with equations 2 and 4 indicates the chief source of error is in the current calculation. That is, when calculated values are finally compared to test results, both current and torque may be off. But when starting amperes by test are substituted in the torque equation, close agreement is brought about. This would indicate a fairly inherent accuracy in the approximations of the torque equations but that current predictions are effected by physical conditions not yet taken into account.

SYMBOLS. (DIFFERING FROM WEST)

$$F=\sqrt{K_r}-K_r\cos^2 A-K_r\frac{\sin^2 A}{\beta^2+1}$$

$H=F+0.5(1-K_r)$

$D=(K_r\beta \sin^2 A)+(\beta^2+1)$

$G=D+p_1(1-K_r)$

$p_1=r_1/X$

$p=r_3/X$

$\beta=r_3/X_0$

C = series conductors on stator

k_w = winding factor, stator

l_c = length of stator conductor in inches

a = resistance of wire in short-circuited coils

r_b = resistance of brush contact in short-circuit path

$$a=\frac{0.5\,Ck_w}{\text{series turns per coil}\times\text{coils shorted under one brush}}$$

$r_3=(r_{\text{coil}}+r_{\text{brush contact}})xa^2$

F. J. Johns (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The resistance of the short-circuited coil circuit is the most difficult of the constants to calculate. Mr. Trickey has called this resistance r_3.

Usually the brush width is slightly less than two commutator bars. In this case several conditions can exist at starting. One or more brushes may be on only two bars in which case only one coil will be shorted. One or more brushes may be on three bars in which case several coils will be shorted. From the number of bars in the commutator and brush width the condition of maximum number of coils should be calculated as this will give the minimum torque at the instant of starting.

A quite satisfactory method of calculating r_3 is to calculate the voltage across the shorted coils. This can be done from primary flux, turns in shorted coil, Kw_3 of shorted coil, and position of coil determined by brush shift. From this voltage subtract the brush drop which is about 1.5 volts for normal brushes at about 200 amperes density or use a curve for the brush in question and at the pressure used on the motor. This voltage divided by shorted coil impedance will give the current. It is usually assumed that the reactance is small so the resistance alone is used. Dividing the total voltage of coil by current will give the value of r_3 to be used. The transformation ratio must be applied to reduce to primary circuit.

As a check the short-circuited current plus the load current can be added to get brush density. If considerably different from assumed density of 200 amperes per square inch, a new calculation of r_3 can be made.

A very important point which should not be overlooked is the change in total flux in the motor. At start this flux is a maximum and as rotor speeds up the flux is reduced. However, this may not be as important on a small motor as it is on a larger one. The magnetizing voltage may be reduced as much as 20 per cent from start to full load on a repulsion-start and run motor.

C. G. Veinott (Westinghouse Electric and Manufacturing Company, Lima, Ohio): In figure 10 of this paper, Mr. Trickey shows the variation of contact drop and contact resisitvity in terms of the amperes per square inch of contact area. This curve shows a wide variation in contact resistance with brush density and might, therefore, throw suspicion on the correctness of assuming a constant-contact resistance in the performance calculations. Apparently the brush curves shown by the author were taken under steady conditions, that is with the particular current density maintained until the voltage drop had become constant. This is the usual manner of taking brush-drop curves. What really should be used in this paper is the dynamic characteristic curve, that is the relation between brush drop and brush resistance when the current density is varied very rapidly; I believe that such curves have been shown by Hellmund, Ludwig, and Baker.

If the brush-drop curve is taken under conditions of rapidly varying density, the contact resistance does not change as much as shown in figure 10. This being the case, Mr. Trickey's assumption that the contact drop does not vary with the current, therefore, more nearly represents the actual conditions than would appear from inspection of figure 10.

A word of commendation should be given the author for giving his calculation schedule in figure 12, which makes it very easy for anyone to use his method without fear of an error in applying the method. Also, his curves figures 2 to 9, inclusive, are enlightening as to some of the characteristics of the repulsion motor.

Performance Calculations on Capacitor Motors—the Revolving-Field Theory

Discussion and author's closure of paper 40-153 by P. H. Trickey, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 73–6.

Wayne J. Morrill: See discussion, page 669.

P. L. Alger (General Electric Company, Schenectady, N. Y.): All of the papers on single-phase motors presented today recognize the need for more exact and complete performance calculations; but each author has a different procedure, with its own particular advantages.

One method of attack which has always been attractive to me is that of developing exact formulas or charts for the principal characteristic quantities, such as the maximum torque, on the basis of simplified conditions, and then using approximate formulas to calculate the correction necessary to allow for variations from the assumed conditions. This method was followed in my 1930 AIEE paper on "Induction Motor Performance Calculations." It seems to me that a similar method of attack on the capacitor-motor problem would enable some useful formulas to be derived particularly for the calculation of the breakdown torque.

Exact formulas for the breakdown torque in the case of a plain single-phase motor are available, and it should be a simple matter to prepare a tabular form or a chart for the calculating of this quantity, as a function of the four variables, r_1, r_2, x_1+x_2, and X_m. Core loss may be neglected in this case.

Then, since the employment of a normal capacitor in the auxiliary winding only slightly increases the maximum torque, it should be possible to develop a second formula or chart for the approximate calculation of this increment in the breakdown-torque value. Such formulas would facilitate quick calculations and would also enable the relative effects of various changes in the design constants to be estimated.

L. W. Buchanan (Westinghouse Electric and Manufacturing Company, Lima, Ohio): The apportioning of iron loss and the inphase magnetizing current has caused quite a bit of trouble in the calculation of capacitor motors by the double revolving-field method. In a number of calculations based on constants derived from test values, I have found, as did Mr. Trickey, that the calculated values agreed with test values more closely if the inphase current component of 60-cycle core loss were added to the main phase-calculated values of current for purposes of figuring the input power and current. These values were calculated on the form originated by Mr. Veinott and described in item number 2 in the bibliography of Mr. Trickey's paper. These calculations gave me values which check the main and auxiliary phase watts and amperes within ten per cent, with the main phase watts always having a tendency to be lower than tested values even after adding the 60-cycle iron losses. Does the author in his calculations, obtain the same tendency?

To follow the calculation as outlined in this paper, it is necessary to separate the 60-cycle iron losses from the high-frequency iron losses. I should like to inquire, if the author uses tested values of reference motors, how he separates these losses.

The single-value capacitor motor is often used on variable-speed applications which makes it necessary to calculate the complete speed-torque curve. It seems to me that it might be more accurate to calculate the output torque and then subtract a torque equivalent to the high-frequency loss and the friction and windage loss. The torque corresponding to both of these losses, I believe, will decrease with a decrease in speed of the motor. If one subtracts the high-frequency iron loss and the friction and windage loss from the motor output in watts, he is reducing the output torque by a greater amount for low speeds than he is for high speeds.

For those of us who prefer to do our vector division in polar form the equation taken from Morrill's paper and translated into the terms of this paper of

$$T=R_f(I_m^2+K^2I_a^2+2KI_mI_a\sin\phi)+R_b[2KI_mI_a\sin\phi-(I_m^2+K^2T_a^2)]$$

where ϕ is the angle between the two currents is very convenient for calculating.

A. F. Puchstein (Robbins and Myers, Inc., Springfield, Ohio): Mr. Trickey states that it is not possible to include the stator iron loss in the primary part of the revolving-field equations without making them too complicated, and that good results may be obtained by assuming all of this loss to take place in the main phase external to the machine itself.

In regard to the first of these the performance may be calculated with theoretical accuracy and minimum labor (when low- and high-frequency iron losses are included, with upper harmonics neglected) by the following procedure.

To obtain r_0, select values for low-frequency core loss F_{e1}, and cemf E_{m1} equal to say, $0.85V$, then $r_0 \cong \frac{E_{m1}^2}{Fe_1}$. Next arrange in parallel columns,

Forward field	Backward field
$\frac{1}{r_0} \quad =$	$\frac{1}{r_0} \quad =$
$\frac{-j}{X_m} \quad =$	$\frac{-j}{X_m} \quad =$
$\dfrac{\left(\frac{R_2}{s}\right)-jX_2}{\left(\frac{R_2}{s}\right)^2+X_2^2}=$	$\dfrac{\left(\frac{R_2}{2-s}\right)-jX_2}{\left(\frac{R_2}{2-s}\right)^2+X_2^2}=$
$\text{Sum}=g_f-jb_f$	$\text{Sum}=g_b-jb_b$
$Z_f=\frac{g_f+jb_f}{g_f^2+b_f^2}=$	$Z_b=\frac{g_b+jb_b}{g_b^2+b_b^2}$
$=R_f+jX_f$	$=R_b+jX_b$
$R_{11}=R_f-R_b$	$X_{11}=X_f-X_b$

$$\begin{array}{rr}
r_{1M}=(\quad) & X_{1M}=(\quad)\\
R_f=(\quad) & X_f=(\quad)\\
R_b=(\quad) & X_b=(\quad)\\
\hline
R_{1M}=(\quad) & X_{1M}=(\quad)\\
-X_{11}=-(\quad) & +aR_{11}=(\quad)\\
\hline
(\quad) & +j\quad(\quad)
\end{array}$$

= numerator for I_M

$$\begin{array}{rr}
r_{1S}=(\quad) & X_{1S}=(\quad)\\
a^2R_f=(\quad) & a^2X_f=(\quad)\\
a^2R_b=(\quad) & a^2X_b=(\quad)\\
R_c=(\quad) & X_c=-(\quad)\\
\hline
R_{1S}=(\quad) & X_{1S}=(\quad)\\
+X_{11}=(\quad) & -aR_{11}=-(\quad)\\
\hline
(\quad) & +\ j\quad(\quad)
\end{array}$$

= numerator for I_S

$$\begin{array}{rr}
+R_{1M}R_{1S}=(\quad) & \\
+a^2X_{11}^2=(\quad) & +R_{1S}X_{1M}=(\quad)\\
-X_{1M}X_{1S}=(\quad) & +R_{1M}X_{1S}=(\quad)\\
-a^2R_{11}^2=(\quad) & -2a^2R_{11}X_{11}=(\quad)\\
\hline
(\quad)\quad + & j\quad(\quad)
\end{array}$$

= denominator for I_M and I_S

Currents:

$$I_M=V\cdot\frac{\text{numerator for } I_M}{\text{denominator}}=A+jB \quad (B \text{ is negative})$$

$$I_S=V\cdot\frac{\text{numerator for } I_S}{\text{denominator}}=g+jh$$

Symmetrical components:

Positive sequence

Current, $I_{m1}=\frac{I_M-jaI_S}{2}$ (vectors)

Cemf, $E_{m1}=2I_{m1}Z_f$ (absolute)

Negative sequence

$$I_{m2}=\frac{I_M+jaI_S}{2}$$

$$E_{m2}=2I_{m2}Z_b$$

Low-frequency core loss (theoretically accurate components),

$$Fe_1=\frac{E_{m1}^2}{r_0}\text{ watts}$$

$$Fe_2=\frac{E_{m2}^2}{r_0}\text{ watts}$$

Internal torques:

$$\begin{array}{lr}
G=2a(Ah-Bg)= & (\quad)\\
I_M^2= & (\quad)\\
a^2I_S^2= & (\quad)\\
\hline
\text{Sum}_f= & (\quad)
\end{array}$$

$$\begin{array}{lr}
-G= & -(\quad)\\
I_M^2= & (\quad)\\
a^2I_S^2= & (\quad)\\
\hline
\text{Sum}_b= & (\quad)
\end{array}$$

$$\begin{array}{lr}
T_f=\text{Sum}_f\times R_f & =(\quad)\\
T_b=\text{Sum}_b\times R_b & =(\quad)\\
\hline
T=T_f-T_b & =(\quad)
\end{array}$$

$$T_{F\&W}=\frac{F\&W}{1-S}$$

$$T_{Fe}=\frac{Fe\text{ high frequency}}{1-S}$$

Shaft torque:

$T_0=T-T_{F\&W}-T_{Fe}$ synchronous watts

$$\text{oz-ft}=\frac{112.6\times T_0}{\text{syn.}}$$

Shaft output:

$=W_0=(1-s)T_0=(\quad)$ watts

Input:

$W_t=V(A+g) \quad =(\quad)$ watts

Losses:

$W_L=W_t-W_0$ watts

For checking,

Pri. copper loss, M	$=I_M^2r_{1M}$	$=(\quad)$	watts
Pri. copper loss, S	$=I_S^2r_{1S}$	$=(\quad)$	watts
Capacitor loss	$=I_S^2R_C$	$=(\quad)$	watts
Sec. forward loss	$=sT_f$	$=(\quad)$	watts
Sec. backward loss	$=(2-s)T_b$	$=(\quad)$	watts
F & W loss	$=$estimate	$=(\quad)$	watts
Fe forward loss	$=\frac{E_{M1}^2}{r_0}$	$=(\quad)$	watts
Fe backward loss	$=\frac{E_{M2}^2}{r_0}$	$=(\quad)$	watts
Fe high frequency loss	$=$estimate	$=(\quad)$	watts
Total loss	$=W_L$	$=(\quad)$	watts

As pointed out in Trickey's paper, it is difficult to make both sets of figures agree in slide-rule calculations.

When the symmetrical components I_{m1} and I_{m2} are known, an alternate way to find the internal torques is,

$$\frac{1}{r_0}=g$$

$$\frac{-j}{X_m}=-jb$$

$$\underline{\qquad}=$$

$$\text{Sum}=g-jb$$

$$Z_\varphi=\frac{g+jb}{g^2+b^2}=R_\varphi+jX_\varphi$$

$$\begin{array}{l} Z_{r1}=\qquad\frac{r_2}{s}+jx_2 \\ \hline Z_\varphi+Z_{r1}=\text{sum}=(\qquad) \end{array}$$

$$r_2=2\times\text{Morrill's } R_2$$
$$x_2=2\times\text{Morrill's } X_2$$
$$X_m=2\times\text{Morrill's } X_m$$
$$Z_\varphi=R_\varphi+jX_\varphi$$

$$\begin{array}{l} Z_{r2}=\frac{r_2}{2-s}+jx_2 \\ \hline Z_\varphi+Z_{r2}=\text{sum}=(\qquad) \end{array}$$

The calculation is then completed in the same manner as before.

$$T_f=2\times\frac{|Z_\varphi|^2}{|Z_\varphi+Z_{r1}|^2}\times|I_{m1}|^2\times\frac{r_2}{s}\quad\text{synchronous watts}$$

$$=2\times\frac{|Z_\varphi|^2}{|Z_\varphi+Z_{r2}|^2}\times|I_{m2}|^2\times\frac{r_2}{2-s}\quad\text{synchronous watts}$$

P. H. Trickey: In reply to Mr. Alger, I might say that we do have a means of obtaining breakdown torque which has been developed much in the way he has suggested.

We have a formula for single-phase motors which I believe was largely due to Mr. C. G. Veinott with a correction which I added later for cases of high rotor resistance or high magnetizing current.

$$\underset{\text{(single phase)}}{T_m}=\left(\frac{E}{110}\right)^2\left(\frac{p}{4}\right)\left(\frac{60}{f}\right)\times\frac{326-8.6\left(\frac{r_1+r_2}{X}\right)^2}{r_1+r_2+X}\;\frac{K_r}{1+\frac{r_2^2}{X_0}}\text{ oz-ft}$$

where

E = line volts
P = poles
f = frequency
r_1 = primary resistance
r_2 = secondary resistance referred to primary
X = total leakage reactance $=x_1+x_2K_p$
X_0 = open circuit resistance $=X_m+x_2$
X_m = mutual or magnetizing reactance
$K_r=K_p^2=\frac{X_0-X}{X_0}$

This formula compares with tested values very well for motors of normal proportions.

It is a characteristic of capacitor motors that as the load becomes greater, the capacitor phase shirks its share which is carried by the main phase. With this characteristic in mind, we have developed the approximate formula below.

$$\underset{\text{(capacitor)}}{T_m}=\underset{\text{(single phase)}}{T_m}+\ {}^1/_2FLT\ \frac{\text{rpm at pull out}}{\text{rpm at full load}}$$

If the motor is "balanced" at some other torque than full load, that torque is used in the formula.

Although this formula is very useful and is being used daily in regular design work, its main difficulty is that we do not have good data as to when it does not apply. We do know that when r_2/X_0 is greater than unity, it is obviously in error because the single-phase breakdown torque is zero which would give less than half full-load torque for capacitor pull-out torque, yet the motor would be balanced at full load and operating satisfactorily with additional torque to spare.

In reply to Mr. Buchanan, I have not noticed particularly that one phase tested further from calculation than the other.

We divide the 60-cycle and high-frequency losses arbitrarily except in those cases where we use the more elaborate method of iron loss calculation by Mr. Spooner.

We decrease the sum of high frequency iron loss plus friction and windage as the square of the speed.

Single-Phase Motor Theory—a Correlation of the Cross-Field and Revolving-Field Concepts

Discussion and author's closure of paper 40-151 by C. T. Button, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 507–12.

Wayne J. Morrill: See discussion, page 669.

C. G. Veinott (Westinghouse Electric and Manufacturing Company, Lima, Ohio): It has been observed before that it is indeed strange that the polyphase induction motor is simpler in theory than the single-phase induction motor, while the latter is simpler in construction, exclusive of the starting mechanism. For polyphase motors, one theory suffices, but there are two accepted theories for single-phase motors, based upon revolving-field and cross-field concepts, respectively. Both theories are useful and a knowledge of both points of view is essential. Arnold, it is said, gave a rigorous proof of the equivalence of these two theories in 1909 in a book of his. Kimball and Alger, in their paper referred to by the author, show too that identical results are obtained by the two theories.

Mr. Button's approach is interesting and helpful. He starts out by setting up the equation for the voltage induced in a coil rotating in a stationary pulsating field, somewhat of a cross-field approach. By deft trigonometric manipulations he shows the existence of the same two frequencies found in the revolving-field method of analysis. As the analysis unfolds, the reader discovers that neither concept is used exclusively, but he does get a helpful picture of just what is happening in the rotor bars. The picture is undoubtedly clearer than that obtained from the usual presentation of the cross-field theory in which consideration is given, not to the actual currents and voltages in the individual rotor bars, but to those same currents and voltages *referred to the stator*, wherein the only frequency is line frequency. And for the latter reason, the cross-field theory is often maligned.

Mr. Button makes the interesting comment, obviously true, that the cross field at synchronous speed is produced by the rotor currents resulting from the voltage induced by the backward field.

The "magnetizing effect" to which Mr. Button refers is the number of ampere turns that would be required to set up the fundamental flux if all those ampere turns were concentrated in one full-pitch coil per pair of poles.

While the assumption of parallel lines of flux, as in figure 1, may be convenient for purposes of analysis, and while the radial component of flux must then necessarily be sinusoidal in distribution, this assumption is fraught with pitfalls when one attempts to consider a practical motor in which all the lines of force are substantially radial and there is no important tangential component as shown in figure 1. The danger is rather simply explained: If the available ampere turns in a full-pitch coil are IN, one might easily say, referring to figure 1, that at the point of maximum flux density in a pole pitch, the ampere turns available to produce flux is IN. However, if radial flux is assumed, the *radial* component of mmf throughout the entire pole face is IN, but the sine-wave equivalent mmf at the center of the pole face is $4/\pi\times IN$.

C. T. Button: In the last two paragraphs of his discussion Mr. Veinott has raised some points which apparently need further explanation.

Suppose we have a single concentrated full-pitch coil in the stator, the plane of which lies in the $X-X$ axis. The cross field or field in the $X-X$ axis may be defined as the flux common to stator and rotor which has no net linkage with this stator coil. If we consider the flux crossing the air gap produced by a pair of rotor conductors diametrically opposite and at a given instant lying in the $Y-Y$ axis, then this rotor turn will be at right angles to the above full-pitch stator coil, there will be no mutual inductance, and the rotor turn is said to produce cross flux in the $X-X$ axis. A rotor turn in the same plane as the stator coil however has maximum mutual inductance with the stator coil and can produce no cross field at that particular instant.

If the angle between the rotor turn and the $X-X$ axis at any instant is θ, then the current in the rotor turn multiplied by $\sin\theta$ is a measure of the amount of cross flux produced by that turn. The integration of all such rotor magnetomotive force components producing flux in the cross-field axis is referred to for convenience as the "magnetizing effect in the $X-X$ axis."

If the total integrated rotor magnetizing effect in the $X-X$ axis at any instant should be called $\text{mmf}_{X\text{eff}}$, then we may state the relation

$$\frac{\text{mmf}_{X\text{eff}}}{\phi_X}=\frac{\sqrt{2}i_mT_{\text{eff}}}{\phi_{M_0}}$$

This is the method of the paper and is the basis of equation 23.

The artifice of assuming parallel lines of flux in figure 1 is felt to hold no danger for the purpose of determining at any instant how much of the total flux links a rotating coil where the flux is sinusoidally distributed around the air gap. The flux could be drawn radially where it crosses the gap (which is about two times 0.015 inch out of a total mean path several inches long in the usual case) but that is of insignificant importance—the basic assumption is that there is sinusoidally distributed flux density around the gap.

The stator winding has in general the same current in each conductor and produces substantially sinusoidally distributed flux density by virtue of roughly sinusoidal distribution of conductor density. The rotor conductors being linearly distributed however can only produce sinusoidal flux distribution at the instant when the primary flux is zero by virtue of roughly sinusoidal distribution of current in the individual rotor bars. When the total cross flux is maximum, the maximum flux density in the gap is at the X–X axis, and the density at the Y–Y axis is zero.

Naturally a single full-pitch coil with ampere turns IN would not produce sinusoidal flux distribution, and the parallel flux lines of figure 1 would not in any way represent that situation. Thus there should be no danger of the possible pitfall suggested by Mr. Veinott. Figure 1 of course is not to be taken to represent a motor but merely a coil rotating in a uniform field periodically varying in density; and it is stated that the resulting voltage in the coil is obviously the same as that which would result in two opposite rotor conductors rotating in an alternating (but not rotating) primary field with sinusoidally distributed density and with cross field zero at all times.

Design Factors Involved in the Design of Domestic Motored Appliances

Discussion and author's closure of paper 40-154 by L. C. Packer, and presented at the AIEE Middle Eastern District meeting, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941, pages 500–07.

Wayne J. Morrill: See discussion, page 669.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The author gives in figure 1 a rather interesting curve of torque-time relations for a refrigerator, which is also typical of conditions in connection with air conditioning. The time schedule is probably omitted intentionally, because under different conditions of service and size the total time varies considerably, thus making the time value for an individual case, such as given in the figure, of secondary interest. It should be noted, however, that the maximum torque in the particular case is 185 per cent of the normal torque, and also that torques exceeding 150 per cent prevail for more than one-fourth of the time. These are overloads appreciably in excess of those usually encountered with motors of this type, and it is therefore likely that in the designing of a motor this pull-down condition is of greater importance than the regular load from a heating point of view. It would therefore seem very desirable for designers of such equipment to determine the practical limits between which the pull-down time varies for various sizes of motors and also how often this condition may be encountered in a given period of time. Without a knowledge of at least the limiting conditions, especially the maximum, it will be difficult to work out safe and economic applications of motors for this service.

E. M. Carville and E. P. Codling (Westinghouse Electric and Manufacturing Company, Lima, Ohio): As motor design engineers, working in a strictly motor manufacturing plant, we wish to add a few thoughts as we look at the problem from a slightly different viewpoint, that of a manufacturer of a wide variety of motors. Our problem is to design motors to be manufactured for use on a number of customer appliances, all of which are different, yet we must use a minimum number of parts in order to facilitate manufacture and keep the cost and development expense to a minimum. In selecting the motor for an appliance, the designer should give due consideration to the quantity which will be produced. When this is small he should make every possible effort to use a standard motor. This will not only aid in keeping the motor cost low, but will facilitate the manufacture of the product and be more satisfactory to the consumer should any replacement be necessary. When the appliance designer finds it impossible to use a standard motor, he should consult with the motor designer in the early stages of laying out his design. Only with the assistance of the motor designer will it be possible for him to lay out a design which will make it possible for him to use the most economical special motor. Many special features may seem simple to the appliance designer, yet require major modifications in motor manufacture and conversely it may be possible with ease to obtain what appears to be very expensive. A slight change in the appliance design may make it possible to use an entirely different type of motor, possibly not normally manufactured in the rating involved, but entirely suitable and more economical for the particular appliance involved. All of this will be determined by the parts available and the details of the manufacture and tooling which will be familiar only to the motor designer.

It is not necessary on some appliances to apply a motor which will have sufficient starting torque to start the maximum possible load. If the appliance is controlled automatically, and the motor is provided with suitable automatic protection, the protection can be relied upon to disconnect the motor in case it is unable to start the load. A motor so applied may be satisfactory if the load will be reduced to a suitable value for starting in a short time. Such is the case with many domestic refrigerators today. If the appliance is manually controlled and proper instructions are given the same may be true. For example, the motor need not be able to start an ironer when the shoe is against the roll. In this position, it would quickly scorch the roll or the material to be ironed, during the time the switch is being closed and the motor is accelerating. A washing machine motor need not be able to start the machine with the wringer jammed. In case of jamming, during operation, instructions are issued to stop the motor, disengage the wringer and agitator, and restart the motor with only the gear load. The cycle of operation for a washing machine as given by Mr. Packer is somewhat different from that recommended by some washing machine manufacturers in that the suds are formed before adding the clothes, and the motor starts the gear load only.

The refrigerator pull-down load-cycle curve shows a maximum load approximately twice as great as the normal load. This as well as the time to reach this maximum load, and the time to level off, varies considerably with the design of the evaporator, the refrigerant, the cabinet, and the refrigerated temperature. On air-conditioning applications, the maximum load and the normal load may be almost the same. On very low-temperature applications the ratio of the maximum load to the normal load will ordinarily be the greatest. The motor must have sufficient pull-out torque to handle this maximum load under the lowest voltage conditions which will be encountered. This affects the motor design and if the ratio is high makes it impossible to design the motor with the maximum efficiency at the normal load point. High overload capacity of necessity results in poorer performance at light loads. Consideration should always be given by the appliance designer to all possible ways of reducing the maximum load if he wishes to obtain the maximum efficiency of the motor at light loads with the minimum cost.

From Mr. Packer's statement regarding "short hour" rating, one not familiar with these terms might receive the impression that these motors are not suitable for continuous operation. To avoid this, recently these motors are being designated as "high torque" motors. These motors are different from the general-purpose split-phase motors in that they have higher torques and lower performance with a resulting lower cost. They are designed for use on infrequently started appliances where the total cost of operation per hour is of less importance than the first cost.

Mr. Packer gives the impression that reduced voltage will not cause excessive temperature rise. When the motor is operating under a heavy load, reduced voltage may have more effect on motor temperature than increased voltage. It should also be pointed out that the torques of the motor vary as the square of the voltage.

Figures 3 and 4 show curves of motors of different types than figure 2, for the same application. These motors would have higher efficiency and lower starting current, but would be more expensive. If this expense is justified, the use of these types of motor is sound. More generally these two types of motors are used on applications requiring higher starting torque and are designed with 200–500 per cent starting torque.

Motor protection may involve other factors than stopping the operation of the motor, such as (1) operation of a visible or audible alarm while leaving the motor connected to the line, (2) operating as a control circuit to reduce or remove part of the motor load without stopping the motor, or (3) both disconnecting the motor and operating the alarm system.

Manual reset protection is used on those applications where there is some hazard involved in having the device reset and restart the motor automatically. On some applications, such as oil burners, this hazard involves the functioning of other controls after stoppage of the motor and before restarting. A still safer procedure than using manual resetting is to establish a sufficiently long time of resetting that these controls will definitely operate first. This can be accomplished by means of a special device involving storage of heat to prevent rapid cooling of the protector. This has the further advantage of preventing complete stoppage of operation should no one be present to manually reset the protector.

The design of domestic motored appliances is quite an involved problem requiring the careful consideration of many details. This makes it necessary to make many contacts with the manufacturing department, the customer, and the supplier, of which one of the most important is the electrical manufacturer.

L. C. Packer: The author is gratified by the reception given this paper at the meeting and grateful for the discussions which have added valuable information to the paper.

Mr. Hellmund's discussion emphasizes the study necessary to the successful application of motors to refrigeration equipment. There are many different types and sizes of this type of equipment and each has its own load cycle; therefore requiring the designer to make a thorough analysis of the load cycle versus time.

The discussion of Carville and Codling has added considerable detailed information to the paper. In commenting upon some of the items I only wish to add that almost every appliance manufacturer has his own ideas about the instructions put out with his device. Many are not clear and do not anticipate many of the things that the user will sometimes do in the operation of the device. Such a case is the washing machine. While the manufacturer puts out what he thinks are proper instructions, it has been the author's experience that many users perform the sequence of operations substantially as described in the paper because they seem more natural. While I did not so state it, when the soap is added, you will find that a woman almost always forms the soap suds immediately. The users sometimes do not even read instructions and often when they do read them, they do not always understand them; therefore, the appliance manufacturer tries to make his appliance as near foolproof as possible against conditions which can and do exist.

The discussion relative to the range of load on refrigerators covers cases that can exist but the ultimate user pays the bill for poor efficiencies. However, there are cases where high efficiencies exist over a wide range of torque, and are accomplished economically by clever designing.

Carville and Codling state that the author gives the impression that reduced voltage will not cause excessive temperature rise. It was not intended to give this impression because conditions can exist where low voltage will cause overheating. While the author cannot speak for all appliance manufacturers it is known that some of them design their devices to operate over the load range under the minimum and maximum voltage conditions. The motor manufacturer can be of considerable help to appliance designers by pointing out to them conditions such as the one just mentioned.

The motor performance shown by figures 3 and 4 are for refrigerator or air-conditioning applications but of different types than the usual domestic type refrigerator. In some cases low starting current is more important than high efficiency while in others both low starting and high efficiency are important. There are cases also where single-value capacitor motors are used.

In the figures 2, 3, and 4, the starting torques are low because the suction and discharge pressures are permitted to become equal at starting, thus requiring relatively low starting torque as there is no pressure differential to start against. Protection for the equipment is quite important and on the whole, a very good job is being done. However, the motor and appliance manufacturers must of necessity co-operate very closely on the design in order to meet all conditions of manufacture, operation, cost, method of selling and servicing the appliance. The author has had many years' experience in the design of both motors and motored appliances and recommends very strongly that the appliance manufacturer co-operate with the motor manufacturer during the preliminary stages of the design rather than after the design is nearly ready for production. The benefits to be derived are well worth while to the appliance manufacturer.

Single-Phase Induction-Motor Performance Calculation

Discussion and author's closure of paper 40-141 by F. S. Himebrook, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 55–8.

Wayne J. Morrill: See discussion, page 669.

A. F. Puchstein (Robbins and Myers, Inc., Springfield, Ohio): This paper gives curves for reading with less labor, the quantities from the circle diagram and thence to obtain performance in the usual way for any point on the circle. His independent variable is *MN*, figure 1, and the dependent variables *OT*, *TR*, *TH*, in figure 2, and *MT*, *NT*, *OE/OZ*, in figure 3, all for $K_r = 0.93$. A different set would however be required for different values of K_r; $K_r = 1$ less Blondel's leakage factor $= 1 - M^2/L_1L_2$. A related method that requires a different set of curves for each value of slip was given by Puchstein and Lloyd in ELECTRICAL ENGINEERING, October 1937, pages 1277–84. Other available methods give performance in terms of slip, rotor input, or shaft output. In figure 2, line *TR* apparently should be a curve. For everyday use, the curves would need to be extended and drawn to a larger scale.

At pull out, the complete performance and speed can be obtained. Ordinarily only the pull-out torque or S_{po} are wanted. The latter is convenient if formulas based on slip are to be used. In figures 4–6, the independent variable is K_r, and the dependent variables *OT*, *TR*, *MT*, *NT*, *MN*, *TH*, *OE/OZ*. To obtain the speed at pull out we have available,

1. Sumec's old value $S_{po} \cong 0.576 \cong \frac{1}{\sqrt{3}} \times \sqrt{2 - \frac{1}{\sin^2 \eta}}$ (1903)

2. Branson, T bisects arc VL in figure 1, AIEE (1912)

3. Veinott, equations and curve based on (2) AIEE (1932)

4. Analytical values based on $\frac{\delta T}{\delta S} = 0$ which are not available, but an approximation based on the cross-field theory when primary local impedance and cross-field losses are neglected is,

$$T \cong \frac{E^2 r_2 (S - S^2)}{r_2^2 + x_2^2 (1 - S^2)^2} \quad \text{syn. watts}$$

where

E = cemf
r_2 = secondary resistance, cross-field value
x_2 = secondary leakage reactance, cross-field value
S = speed with synchronism as unity

Placing the derivative of T with respect to S equal to zero gives

$$S^6 - S^4 - S^2\left(1 + 3\frac{r_2^2}{x_2^2}\right) + \left(1 + \frac{r_2^2}{x_2^2}\right) = 0$$

The following table gives the speeds at pull out obtained from this equation.

$\frac{r_2}{x_2}$	S	$\frac{r_2}{x_2}$	S
0.0	100	1.2	66.4
0.1	95	1.3	65.2
0.2	90.5	1.4	64.5
0.3	86.6	1.5	63.9
0.4	82.8	1.6	63.2
0.5	79.4	1.7	62.6
0.6	76.5	1.8	62.1
0.7	74.2	1.9	61.8
0.8	72.0	2.0	61.4
0.9	70.3	2.5	60.2
1.0	68.5	3.0	59.5
1.1	67.3	∞	57.7

F. S. Himebrook: Mr. Puchstein's reminder that additional sets of curves for figures 2 and 3 are required for each different value of K_r, indicates that probably not enough stress was given the total number of curves required. When the set of curves was prepared it was found that in some cases ($K_r \leqq 0.90$) it was necessary to use values differing from one another by one per cent. However, for other values ($K_r < 0.90$) it was necessary to prepare sets of curves in which the value of K_r was changed by only one-half of one per cent. Such a procedure was necessary to maintain as high a degree of accuracy as possible.

In figure 2, the line *TR* is actually a curve as Mr. Puchstein points out. However, the deviation from linearity in the range shown in figure 2 is slight (a maximum of approximately 1.5 per cent). This is true because *TR* is a function of the sine of angle *NHM* (figure 1) and since this angle, for the range shown, does not exceed 11 degrees there is present only a small deviation because in this range the angle and its sine are approximately equal. If the range were extended the departure from linearity would become apparent.

The curves were originally plotted on standard $8^1/_2$ by 11-inch co-ordinate paper and in such work the accuracy of plotting was as great as the accuracy of the values read from the circle diagram.

The range of the curves for the motor whose constants are given in table I is from no-load to about 13 per cent slip. This value is well beyond the normal operating range because most single-phase induction motors are designed to operate at a relatively small slip.

The motor whose constants are shown in table I showed a pull-out speed of approximately 1,450 rpm. The speed calculated by the method described in this paper was found to be 1,415 rpm. A calculation using the method described by Mr. Puchstein yielded a somewhat lower figure.

The writer has recently learned that W. J. Branson (in some unpublished work) has succeeded in locating the center of arc *VLH* (figure 1) mathematically. This would permit an entire set of performance data to be calculated without constructing an actual circle diagram although the method uses the circle diagram as its basis.

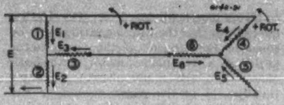

Figure 1

(1)—$E_1 = I_1(Z_1+Z_f+Z_b)+I_2(Z_f+Z_b+jX_1)+aI_3(-jZ_f+jZ_b)$

(2)—$E_2 = I_2(Z_1+Z_f+Z_b)+I_1(Z_f+Z_b+jX_1)+aI_3(-jZ_f+jZ_b)$

(3)—$E_3 = I_3(Z_2+a^2Z_f+a^2Z_b)+a(I_1+I_2)(jZ_f-jZ_b)$

(4)—$E_4 = I_4(Z+Z_f+Z_b)-j\frac{X}{2}(I_5-I_3)+I_5(Z_f\epsilon^{j\beta}+Z_b\epsilon^{-j\beta})-I_3(Z_f\epsilon^{-j\beta}+Z_b\epsilon^{j\beta})$

(5)—$E_5 = I_5(Z+Z_f+Z_b)-j\frac{X}{2}(I_4-I_3)+I_4(Z_f\epsilon^{-j\beta}+Z_b\epsilon^{j\beta})-I_3(Z_f\epsilon^{j\beta}+Z_b\epsilon^{-j\beta})$

(6)—$E_6 = -I_3(Z+Z_f+Z_b)-j\frac{X}{2}(I_4+I_5)+I_5(Z_f\epsilon^{-j\beta}+Z_b\epsilon^{j\beta})+I_4(Z_f\epsilon^{j\beta}+Z_b\epsilon^{-j\beta})$

(7)—$E = E_4 - E_5$

(8)—$E = E_1 + E_2$

(9)—$E = E_3 + E_4 - E_6 + E_2$

(10)—$I = I_1 + I_4$

(11)—$I = I_2 - I_5$

The Cross-Field Theory of the Capacitor Motor

Discussion and authors' closure of paper 40-140 by A. F. Puchstein and T. C. Lloyd, presented at the AIEE Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940, and published in AIEE TRANSACTIONS, 1941 (February section) pages 58–62.

Wayne J. Morrill: See discussion, page 669.

E. J. Schaefer (General Electric Company, Fort Wayne, Ind.): In this paper, the authors have made certain comparisons between the cross-field theory, the method used by them, and the revolving-field theory of the capacitor motor which was presented some years ago by W. J. Morrill.

With identical assumptions, of course, the final results must be the same, regardless of the method of analysis used. Whether there is any advantage of one method over the other down to the point where they converge to a common result seems to me dependent almost entirely on individual preferences and relative familiarity. There are certain advantages stated by the authors to be inherent in the cross-field theory, however which are based on assumptions that are not rigid and therefore do not actually provide the advantages mentioned.

I believe, for instance that there is too much of a tendency to regard the two axes into which the machine is broken down as actual physical fact rather than analytical artifice. I believe that this tendency is evidenced by the statement that it is easier to visualize differences in saturation and core losses in the two axes by the cross-field theory.

It must not be forgotten that the fluxes in the two axes in fact do *not* exist separately and that in the presence of unequal saturation the fluxes in the two axes cannot be assumed to remain independent of each other which is a basic assumption on which this method of analysis depends. To take into account different saturations in the two axes in making calculations is an attempt to take out of the formulas more than was included in the original assumptions and therefore cannot give correct results.

In visualizing these component fields as separate and physical entities there is also the danger of considering that one or the other represents the maximum flux axis. This, of course, is not the case, for, at some angle between the main and start axis there will be found, by properly adding the two components, an axis of maximum flux, and, 90 degrees displaced from this on axis of minimum flux.

$$\Phi_{max} = \Phi_M \cos\phi + \Phi_S \sin\phi$$

when

$$\tan 2\phi = \frac{2(\Phi_M \cdot \Phi_S)}{|\Phi_M|^2 - |\Phi_S|^2}$$

where Φ_M and Φ_S = vector, main, and cross-axis flux respectively.

In the case of the revolving field point of view Φ_{max} is obtained merely by the addition of the scalar values of forward and backward components.

$$\phi = {}^1/_2\phi'$$

where ϕ' = phase angle between Φ_f and Φ_b, the forward and backward rotating components of flux.

As for more exact methods of allowing for core loss, if it is desired to make allowance by means of an equivalent shunt resistance this resistance may be placed in parallel with X_M with equal facility by either method. There is very seldom a case where the gain in accuracy by this method is worth the extra effort.

As far as the final results at least are concerned, the capacitor-motor analysis has now become quite a familiar story. However, we have the opportunity to test the utility of the analytical tools made available by these studies on different and more complicated problems. One of these, which we recently had occasion to solve and which yielded nicely to the revolving field method of attack was that of a T-connected single-phase teaser motor furnishing unbalanced three-phase power to a conventional polyphase motor. The problem was to calculate the torque characteristics of the T-connected machine with three-phase motor standing still and with one line open; then with line closed to calculate the torque characteristics of the three-phase motor with the T-connected machine running. figure 1 shows schematically the arrangement with the equations which must be solved.

Figure 2 shows comparison of test and calculated torque values for the three-phase motor with the single-phase teaser motor running at a high speed. For each speed of the teaser motor there would, of course, result a different speed-torque curve for the three-phase motor.

C. G. Veinott (Westinghouse Electric and Manufacturing Company, Lima, Ohio): One cannot help agreeing with the conclusions of the authors regarding the inadequacy and inconvenience of the existing design tools for capacitor motors. For this reason this paper is particularly noteworthy. The cross-field theory has already been applied to single-phase induction motors by a number of different authors, and also to repulsion motors. Therefore, it seems only logical to develop it for capacitor motors as well, since the cross-field theory does have certain advantages. This paper is also particularly noteworthy and helpful in that the authors compare their methods with previous methods and give numerical comparisons of the results as computed by the different methods, their own included. Would that this were done more often!

The authors state that "the cross-field theory is blind to the existence of two separate skin effects in rotor conductors and to a pulsating torque superposed on a steady torque." The authors are correct in that, in the usual treatment of the cross-field theory, all of the rotor voltages and currents are referred directly to the stator, wherein line frequency only exists and thus sight is lost of the two separate frequencies in the individual rotor bars. However, Mr. Button, in his paper, shows that the cross field necessarily need not be blind to the two individual rotor frequencies; he shows this, by dealing with individual currents and voltages in the rotor bars themselves, instead of referring these voltages and currents directly to the stator before cognizance is taken of the two frequencies.

The authors' statements that the cross-field theory is blind to the existence of the pulsating torque is a little surprising since Kimball and Alger (AIEE Transactions, June 1924, pages 730–9) develop formulas for the pulsating torque from the cross-field theory.

The authors refer to a relationship given by Punga and Krondl relative to the ratio of turns in the main and starting windings to give a true revolving field. The relation quoted was that the winding ratio should be equal to the tangent of the power-factor angle of a two-phase motor with both phases like the main phase. Trickey's equation 11 in the paper quoted by the authors gives the same identical relationship if the losses in the capacitor are negligible, also if there are equal weights of copper in the main and starting windings. Anyone using Trickey's formula will see that this relationship is approximately true, even if the weight of copper in the two windings is not the same; as a matter of fact, I often make this as the first assumption when making a design calculation on a capacitor motor.

Edward Bretch (The Advance Electric Company, St. Louis, Mo.): In the theoretical consideration of the single-phase squirrel-cage motor it is rather difficult to reconcile some of the assumptions with practical conditions.

In the two-field theory it is assumed that two rotary fields of half the amplitude of the single-phase field, rotating at equal speeds in opposite directions is the equivalent of a single-phase field.

In a single-phase field the flux goes through zero twice during each cycle. As the flux is confined to one path only, all components must go through zero when the total flux does as all flux disappears at the moment of reversal. Thus all components of a single-phase flux must also go through zero and since all components go through zero there could be no rotary components as a rotary field does not go through zero but shifts its position. It is generally admitted that a polyphase system cannot be transformed directly into a single phase, or the reverse, since the polyphase represents a continuous flow while the single phase is intermittent.

It would seem that the same reasoning would apply to magnetic fluxes and it is difficult to see how a single-phase field can have any rotary components. Experiment also indicates that the single-phase field cannot be resolved into oppositely rotating components. If two similar polyphase windings are placed in the same slots of a field structure and an attempt is made to connect them to a polyphase source of power so as to cause the fields to rotate in opposite directions, a short-circuited condition develops.

In the cross-field theory it is assumed that voltages induced in the rotor conductors as they cut across the primary or transformer field set up currents that produce a cross flux at right angles to the transformer flux both as to time and space. This speed field is assumed to vary directly with the speed, being zero at standstill and equal to the transformer field at synchronism thus producing a true rotary field at synchronism.

Assuming synchronous conditions, at the instant the transformer flux as well as the primary current are zero the speed field is at its maximum. It is evident that this cross field must be due to rotor currents, as the primary current is zero. It is also evident that these rotor currents producing it are at their maximum since flux and the exciting current coincide. It is difficult to see how the current due to a speed action would be at a maximum when the flux was zero. This condition indicates that the cross or speed flux is due to a transformer action. Also, if the speed action of the rotor conductors is required to produce the cross field, what produces the torque?

While the theory of the single-phase squirrel-cage motor is difficult to master the practical operation is not difficult to understand.

In synchronous motors and generators it is a common practice to use amortisseur windings. These are simply low-resistance grids or squirrel cages embedded in the pole faces. They are used for two general purposes: (1) to prevent sudden shifting of the flux across the pole faces as for example to prevent "hunting" and (2) to dampen out field-flux pulsations as for example to stabilize the field of a synchronous generator against pulsating single-phase armature reactions.

In a single-phase squirrel-cage motor at synchronism the primary-field excitation sets up a flux in the rotor as well as in the stator. The squirrel cage which is moving in synchronism with the field excitation forms a most effective amortisseur winding by which induced currents sustain the rotor flux substantially constant during the time the primary excitation goes through zero and the rotor moves from pole to pole. Thus these amortisseur currents sustain the rotor flux, and the mechanical rotation of the rotor carries this sustained flux around with it producing the typical rotary field of the single-phase motor. Under running conditions the rotor runs slightly below synchronism. Each time a rotor pole approaches a stator pole the primary magnetizing force pulls the rotor field into synchronism and due to the same action as a polyphase motor tends to pull the rotor along with it, producing the torque. Thus the torque is a series of impulses one for each primary current impulse or of double frequency.

These observations indicate the following:

(1). The cross field is produced by the mechanical rotation of a substantially constant rotor flux.

(2). The rotor flux is sustained while the primary excitation goes through zero by the amortisseur action of the squirrel cage.

(3). These flux-sustaining amortisseur currents are of double frequency at synchronism as they go through a complete cycle while the rotor passes from pole to pole. At speeds below synchronism they are double frequency less slip.

(4). The torque is a series of impulses of double frequency in step with the primary magnetizing impulses.

A. F. Puchstein: We are in agreement with the points raised by Mr. Veinott. With reference to the pulsating torque, in the preparation of this paper we had in mind the fact that the two rotor frequencies have disappeared from the analysis when the equations are put in the form of Steinmetz or West. The cross-field theory then is blind to their existence. Of course these two frequencies can be preserved by some such method as those of Biermanns, Kimball and Alger, or Button, in which instantaneous values are used as pointed out in the paper.

On the matter of balanced operation, we have hitherto missed the equivalent of the relation $a = \tan \phi$ in Trickey's 1932 paper. It is not immediately apparent from his equation 11 but when reduced, with $R_s=0$, it does give

$$a=\frac{V \sin \phi - I_M r_{1M} K_s}{V \cos \phi - I_M r_{1M}}$$

For equal copper this is approximately equal to the tangent, as Mr. Veinott's statements indicate.

Mr. Schaefer points out the danger of visualizing the main and cross fields as separate entities which do not react upon each other. Actually, saturation effects cause them to interfere somewhat with each other. However, his expression for tan $2\phi_1$ makes ϕ_1 a complex quantity whereas it actually is real. The following would seem to be a true analysis.

If ϕ_1 indicates any point on the yoke counted from the center of the S-axis then the yoke flux at this point for any instant t is

$$\Phi = -0.5\Phi_M \sin \omega t \cos \phi_1 + 0.5\Phi_S \times \sin(\omega t+\phi') \sin \phi_1 \qquad (1)$$

The time at which the maximum or minimum flux takes place and the location in the yoke is found by taking the derivatives

$$\frac{\delta\Phi}{\delta(\omega t)} \text{ and } \frac{\delta\Phi}{\delta\phi_1}$$

and equating them to zero. The angle ϕ' used here is the time angle between the main and cross-axis fluxes. ϕ_1 is Mr. Schaefer's ϕ.

The maximum or minimum of Φ occurs at ϕ_1 when ωt has the values given by

$$\tan \phi_1 = \frac{-\Phi_M \cos \omega t}{\Phi_S \cos(\omega t+\phi')} \qquad (2)$$

Also, at time t the flux Φ is a maximum or minimum when ϕ_1 has the values given by

$$\tan \phi_1 = \frac{\Phi_S \sin(\omega t+\phi')}{\Phi_M \sin \omega t} \qquad (3)$$

The values of ωt which satisfy both of these relations are given by equating, so that

$$-\frac{\Phi_M}{\Phi_S}\cdot\frac{\cos \omega t}{\cos(\omega t+\phi')} = \frac{\Phi_S}{\Phi_M}\cdot\frac{\sin(\omega t+\phi')}{\sin \omega t} \qquad (4)$$

From this, the flux Φ is a maximum or minimum at the times ωt given by

$$\frac{\sin 2(\omega t+\phi')}{\sin 2\omega t} = -\left(\frac{\Phi_M}{\Phi_S}\right)^2 \qquad (5)$$

and these maxima or minima exist at the locations given by (3).

Mr. Schaefer also comments on the core loss, suggesting that the accuracy gained by its consideration is not usually worth the effort involved. It has been our experience that the neglect of such loss on small motors seriously interferes with the accuracy to be expected between calculated and test values. It is our belief that the iron loss can be included with theoretical accuracy and little increase in labor, as illustrated in my discussion of Trickey's current paper.

Wayne J. Morrill (General Electric Company, Fort Wayne, Ind.): The papers of this session seem to center so much about the thought of comparing the cross-field theory with the revolving-field theory that I should like to discuss at one time and in a general way the papers by Ager, Puchstein and Lloyd, Trickey, Button, Packer, and Himebrook. I should like to direct my discussion toward the central theme and consider the general merits of the two theories under consideration.

It has been proved and for a long time accepted that the current voltage equations obtained by means of the revolving-field theory are equivalent to those obtained from the cross-field theory. In other words the results arrived at by both lines of reasoning are identical and the end equations obtained through the use of either method can be expressed in the language of the other by mathematical transformation.

It might be questioned why two approaches should be used to attain the same end and it might further be questioned as to whether one of these theories does not have important advantages over the other. In view of these natural questions I should like to consider what a good theory should be expected to do.

In my opinion some of the advantages which we should expect of a good motor theory are:

1. A good theory should present an *accurate* picture by means of which mathematical expressions for the current torque, etc., may be obtained.

2. It should furnish the *simplest possible* picture concerning the important phenomena consistent with the accuracy desired.

3. The theory should furnish *means for readily considering the effects of minor phenomena* when such consideration becomes necessary or desirable.

4. It should, if possible, present a picture *readily susceptible to high-handed simplification* for the determination of limiting conditions such as no load, standstill, balanced operation, etc.

5. The theory *should preferably not change form* or require a new mathematical analysis *when slight normal modifications* of structure are made.

6. Finally, if with no extra complication, the theory can *show the relation between the motor in hand and motors of other types* this is desirable, particularly in an operating design department where motors of many types and connections must be handled simultaneously.

Undoubtedly there are other considerations which should be given to a good theory but these are some that are believed important.

Having proposed a set of considerations by which to compare the merits of alternative motor theories I should now like to consider the relative usefulness of the cross- and revolving-field theories. Throughout the discussion I shall make liberal use of equivalent circuits because through their use information can be set down more compactly and in a form subject to visualization.

1. In the matter of *accuracy* the revolving-field theory and the cross-field theory are equivalent because both give correct expressions for current, torque, etc. On the basis of this consideration the theories are of equal value.

2. The *simplicity* of the one theory as compared with the other is perhaps a matter of personal opinion, though from my own familiarity with both theories I would say that for plain a-c commutator motors the cross-field theory seems the simpler; where both a commutator and a squirrel cage exist, as in a repulsion-induction motor there is probably little to choose between the two basic theories; in the case of induction motors, however, it would appear that the revolving-field theory is simpler. Subsequent comments are directed particularly to consideration of the theories in connection with induction motors.

3. When it is desired to consider minor phenomena such as fundamental stator iron loss or the effect of stator harmonics, the revolving-field theory appears to have some real advantages.

Figure 1*a* shows the complete equivalent circuit for a single-phase motor if the fundamental iron loss is neglected. By the use of "apparent impedances" figure 1*a* may be reduced to the single branch circuit figure 1*b*.

A very close approximation to the effect of stator fundamental iron loss can be made if a suitable resistance is bridged in parallel with each of the forward and backward apparent impedances as shown in figure 1*c*. As in the case of figure 1*a*, figure 1*c* can also be reduced to a single branch circuit by using a new set of apparent impedances as in figure 1*d*. When the apparent impedances, corrected for iron loss, have been obtained the operations required to calculate the current are no more complicated than before. Since it is obvious that stator iron loss does not represent torque, the fundamental stator iron loss of the forward and backward fields must be calculated as E_f^2/R_t and E_b^2/R_t and subtracted from the total forward and backward field losses before using these losses to determine torque.

The effect of stator harmonics is readily determined with the revolving-field theory by first calculating for each harmonic its magnetizing reactance, secondary reactance, and secondary resistance. Using these harmonic constants a single-phase equivalent circuit may be constructed for each harmonic and properly connected in series with the fundamental equivalent circuit as shown in figure 2. (It should be noted that when the harmonic equivalent circuits are employed, the fundamental primary leakage reactance must be reduced by an amount equal to the sum of the forward and backward harmonic magnetizing reactances.) Using the combined fundamental and harmonic equivalent circuit the complete characteristics, including harmonic effects may be determined.

It is difficult to see how the cross-field theory could so simply yield results in connection with the minor phenomena.

4. When it is desired to make high-handed simplifications to quickly determine by inspection what will happen under certain limiting conditions the revolving-field theory really demonstrates its advantage.

At standstill the forward and backward impedances become equal and no current will flow through the central connection and the equivalent circuit figure 1*a* reduces to figure 3*a*. If X_m is very large it may without serious error be assumed infinite and figure 3*b* will apply.

At forward synchronism the slip becomes zero, the forward-field secondary impedance becomes infinite, and the circuit takes the form of figure 4*a* and figure 4*b*. Since the backward slip is 2, the backward secondary impedance is usually very low with respect to X_m and without serious error the circuit may be represented as in figure 4*b*. This circuit and the preceding one are useful in obtaining constants from test.

If it is desired to learn the no-load speed (rotational iron and mechanical losses neglected) it is merely necessary to equate the forward and backward field apparent resist-

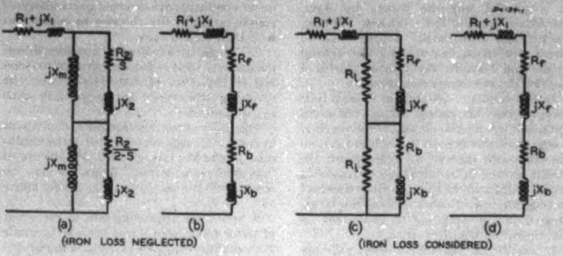

Figure 1. Equivalent circuits for single-phase motors

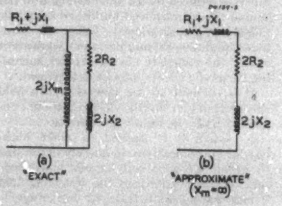

Figure 3. Single-phase motor standstill equivalent circuits

ances and solve for S. A very easy and very accurate approximate method is to assume that at no load the voltages impressed on the forward and backward fields will be the same as at synchronism, figure 4*b*. On this basis the no-load slip may be expressed as:

$$S_{NL}\frac{E_{f0}^2}{R_2}=I_0^2R_{b0} \qquad (1)$$

$$S_{NL}=\left(\frac{I_0}{E_{f0}}\right)^2R_{b0}R_2 \qquad (2)$$

I_0 = input current when $S=0$
E_{f0} = forward field voltage when $S=0$

If it is desired to determine the no-load speed including the effect of rotational losses it is merely necessary to add the rotational losses to the right number of (1).

In a similar way, such questions as, what would happen if the secondary resistance or reactance were zero and what would happen if X_m were made very low, can be readily answered.

5. A modification of induction motor design often resorted to is the multiple cage rotor. The equivalent circuit for a single-phase double cage motor is as shown in figure 5*a*. Again, the multiple branch circuits may be replaced by a single branch circuit through the use of "apparent impedances" as in figure 5*b*. Once these "apparent impedances" have been determined the calculation of performance of a double or triple squirrel cage motor by means of the revolving-field theory is exactly as easy as that of a single cage motor. The same calculation form will handle both calculations. In the case of the cross-field theory, the introduction of a double cage rotor requires a new theory development.

6. As shown in my original paper, when the revolving-field theory is used the current and torque equations for a balanced polyphase motor appear as a special case of the unbalanced motor and the constants and symbols are very closely related. This is advantageous in an operating department in that it permits of handling all induction motors, regardless of type, by means of the same theory. The cross-field theory, on the other hand, bears little resemblance to usual polyphase motor theory.

While the above remarks have been illustrated by the simple case of the single-phase motor they apply in the same way and with relatively the same increase in complication to the split phase motor, the capacitor motor, the unbalanced two-phase motor and, as Mr. Schaefer shows, to even more complicated arrangements such as the "teaser" motor. In all, it can be seen that the revolving-field theory when applied to induction motors is a simple, powerful, and flexible tool.

In conclusion I should like to point out that this very well-attended session indicates a great interest in small motors, which interest is in line with their importance. When we realize that the annual sales of fractional horsepower motors of all types probably amount to about $80,000,000 and that the rated horsepower represented is probably of the order of 3,000,000 horsepower it can be seen that small motors are important. Not only are they important to the motor manufacturers but to the appliance or device manufacturers, the merchandisers, the users, and the power companies. These motors and their related problems deserve a place on AIEE programs.

There are many problems connected with the design and use of small motors which are as yet unsolved. That these problems have a real commercial significance can be appreciated when it is realized that with an annual production of 500,000 motors of one type (there are a number of applications, the motors for which reach these annual quantities) it would be worth while for a good engineer to spend a whole year in order to find a way to save one cent per motor. If possible the reward for good engineering is even greater in connection with mass production small motors than on large apparatus. It is to be hoped that in the future more sessions of this type will be scheduled and, if so, I think we can expect equally great interest.
